Electroencephalography again is useful in following the transition of an acute cerebral abscess into the encapsulated form and the performance of serial electroencephalographic examinations during the waiting period helps to determine when the critical time for operation has been reached.

6 Any case of intracranial infection with streptococci

Any case in which streptococci are identified in the cerebrospinal fluid is a potential case of cerebral abscess. Smith Duthie and Cairns (1946) found 6 of 8 consecutive cases of streptococcal meningitis to have a cerebral abscess. Streptococci in the cerebrospinal fluid therefore demand ventricular puncture and ventriculography and serial electroencephalograms where possible. If an abscess is found direct introduction of penicillin into the ventricles and abscess cavity along the lines here indicated is essential. Even if no abscess is found, repeated intraventricular

Fig. 4. A electroencephalogram showing high voltage (25 mV) slow (2-3 c/sec.) delta waves, such as are seen in the region of cerebral abscess formation after encapsulation. A tracing of this type is an indication for treatment along the lines described in this paper. The record is taken with monopolar leads in the left frontal, motor and occipital regions.

jection of penicillin is the best method of treatment in all cases of streptococcal intracranial infection. No patient with streptococcal meningitis should ever be subjected to lumbar puncture twice after it has been identified as such (Smith, Duthie, and Cairns 1946) the direct ventricular route should immediately be resorted to.

7 Cases in which intracranial operations are to be carried out upon or in the presence of potentially infected foci

Intraventricular injection of penicillin may be used prophylactically as a preoperative procedure, combined if necessary with intraspinal administration of the drug. Its use has been already referred to and Cairns (1945) recommends that a single dose of 4000 to 8000 Oxford units be injected into the ventricles prior to operations for (a) removal of chronic brain abscess, (b) closure of a cerebrospinal fistula, (c) dural repair after orbitofrontal or nasofrontal wounds or lesions involving the petrous temporal bone. This procedure should be used more often as a preliminary to surgical attack on potentially infected craniocerebral wounds particularly those in which intracerebral foreign bodies are present. Cerebrospinal rhinorrhoea is an especial indication for repeated intraventricular injection of penicillin which should be commenced immediately the condition is manifest and continued after its operative treatment.

To conclude this section of the paper the groups of cases which the author believes to

indicate the use of repeated intraventricular injection of penicillin solution are summarized below.

1 Any case of purulent intracranial infection with a penicillin sensitive organism, in which the cerebrospinal fluid pressure and cell counts are high.

2 Any case of intracranial infection with highly virulent or partially penicillin sensitive organisms, especially in children.

3 Any case of intracranial infection with a penicillin sensitive organism which fails to show early and progressive improvement under medical treatment.

4 Any case of intracranial infection with a penicillin sensitive organism in which cerebrospinal fluid block is suspected.

5 Any case in which intracranial abscess formation is suspected.

6 Any case of intracranial infection in which streptococci are found in the cerebrospinal fluid.

7 Any case in which intracranial operations are to be carried out in the presence of potentially infected foci.

8 Any case of head injury that develops cerebrospinal rhinorrhoea.

9 Any case of intracranial infection with a penicillin sensitive organism that develops papilledema.

10 Any comatose case of intracranial infection.

TECHNICAL CONSIDERATIONS.

4 Operative procedure The initial operation is the same as that for the performance of ventriculography two burr holes being introduced into the skull under local anaesthesia, either in the parietal or frontal regions. The diploe of the bone is first inspected for evidence of osteomyelitic infection. The dura is seen in the depths of the burr holes, and, after inspection for evidence of epidural infection or abscess formation is opened with a fine knife and hook. In some cases a subdural empyema may be found overlying the brain (Kubik and Adams, 1943; Spitz and others, 1945). If present this may be drained, and a fine rubber tube inserted and left *in situ*, through which penicillin may be repeatedly instilled into the subdural space. If epidural

or subdural infection is present no attempt should be made to needle the ventricle through the infected locus on that side the opposite side should be utilized.

Brain needles are then passed into the lateral ventricles and the contained fluid is aspirated. A rough qualitative estimate of the intraventricular pressure can be made and compared with that on the opposite side, and the depth at which the ventricle was tapped should be read off from the centimeter scale on the brain needle, as it provides an estimate of the size of the ventricle. A separate needle should be used to tap each ventricle.

The cerebrospinal fluid obtained from each ventricle should be collected in separate sterile containers, and examined individually for volume, turbidity, cell count, protein content and organisms, as this furnishes valuable evidence of the presence or absence of intraventricular block. Further evidence of this and the patency of the foramen of Monro may be adduced by washing sterile Ringer's solution through from one ventricle to the other with both brain needles in place, or by the introduction of methylene blue or filtered gas into one ventricle to see if it will pass to the opposite ventricle. If the fluid obtained from one or both ventricles be turbid, as much of it as possible should be removed by gentle aspiration with a syringe if necessary, and the ventricles should be washed out with warm sterile Ringer's solution until the returning fluid is clear.

If ventriculography is to be performed 10 to 20 cubic centimeters of filtered air or oxygen are injected into one (or both) ventricles, the brain needles withdrawn and the scalp wounds sutured.

The patient remains on the operating table and the requisite radiographic pictures are taken. This procedure outlines the ventricular system disclosing any asymmetry or displacement indicative of an abscess, and assists in the diagnosis of intraventricular block.

When satisfactory films have been obtained the patient still on the operating table, is returned to the theater and a fresh brain needle is introduced into each ventricle through the closed scalp wounds. The con-

tained air is aspirated with a syringe, and 3 to 5 cubic centimeters of penicillin solution containing 10,000 units to the cubic centimeter is injected after dilution with 5 to 10 cubic centimeters of warm saline, if desired. At first, in view of reports of reactions to intrathecal injection of concentrated penicillin solutions (*vid sup*) high dilutions were employed for intraventricular injection of the order of 500 to 1000 units per cubic centimeter, Cairns (1945) recommended 2000 units per cubic centimeter. Now however "pure" penicillin solution as supplied by The Commonwealth Serum Laboratories in concentrations of 10,000 units per cubic centimeter is injected without further dilution directly into the ventricles in amounts of up to 5 cubic centimeters, no reactions to this procedure have been seen on the now numerous occasions on which this has been done, even in babies.

B Postoperative management. On completion of this procedure the patient is returned to bed after the wound is dressed and subjected to the usual postoperative routine. A course of systemic sulfadiazine (4 gm *statim* then 2 gm in 4 hours, and 1 gm. fourth hourly thereafter) is begun, if not already commenced. If desired parenteral administration of sulfonamide may be instituted in the early critical stages. Fluid balance charts are rigorously kept and fluids given by intragastric or intravenous drip methods on the slightest pretext.

Some of these patients become very restless or even delirious following the preliminary operation and should be restrained with cuffs on legs and arms and bedrails if necessary. Sedation may be accomplished with repeated intramuscular injections of dial in doses of 1 to 2 cubic centimeters with or without paraldehyde given orally or *per rectum*. In very restless patients, especially if at all dehydrated a Ryles tube may be passed and left *in situ* after restraint has been arranged and through this fluids and paraldehyde may be introduced as required.

In those cases in which there is persistent cerebral edema especially those that have preoperative papilledema, in which the cerebrospinal fluid pressure often remains high rectal hypertonic solutions may be given. For

Fig. 5. The clinical chart of case of purulent meningitis and ventriculitis due to *Staphylococcus aureus*, treated with 9 daily intraventricular injections of penicillin. The rapid recovery following institution of this method of treatment is well seen. The clinical course prior to this was fluctuating, with gradual trend for the worse under a month's medical treatment with sulfonamides and systemic and intrathecal penicillin (from Wyke and Vanderfeld, 1946) Pulse, black line, temperature later ruptured line.

adults 6 ounces of magnesium sulfate in 50 per cent solution may be given every 8 to 12 hours and retained. In the case of young children and babies, a rectal hypertonic saline solution is used prepared in the following manner: 6 drachms of 17½ per cent saline solution are made up to 2 ounces with distilled water making a sufficiently hypertonic solution which can be given at repeated intervals until the pressure inside the skull returns to normal. A useful indication of cerebral edema, which may be marked postoperatively is a rapid fall in cerebrospinal fluid pressure after withdrawal of only a small volume of fluid at spinal drainage. If cerebral edema is marked treatment by spinal drainage is of little avail and intravenous injections of up to 50 cubic centimeters of hypertonic sucrose should be given.

Each day in the ward a brain needle is introduced into the alternate ventricle (if

there is no block) or into both ventricles (if there is an intraventricular block) and the cerebrospinal fluid gently aspirated with a syringe. A cell count and culture is done on each specimen of fluid removed each day for control purposes and the results graphed, if required. Such a graph (of the pressure and cell count) is a useful index of the efficacy of treatment. After the fluid is removed the ventricle is washed out with warm Ringer's solution and the penicillin is introduced in the same strength and amount as before. Then the wound is redressed.

A mask should be worn and sterile gloves donned before commencing the procedure. The patient is postured on his side, with the head flat and slightly flexed so that the burr hole to be tapped is uppermost. The dressings are then removed with sterile forceps by a nurse, and the field is swabbed with metaphen and covered with a sterile area sheet. The

sutures in the wound are not interfered with, the burr hole being easily found with the point of the brain needle. At the same time lumbar puncture may be performed and penicillin instilled intrathecally, although in most cases this is an unnecessary adjunct.

The procedure detailed is repeated daily until the cerebrospinal fluid pressure falls to normal limits and the fluid becomes clear, the cell count in the ventricular fluid is within normal limits, and the cultures of fluid from each ventricle are sterile on three successive occasions. Considerable improvement is usually apparent within 2 to 4 days and in most cases not more than 6 to 9 intraventricular injections are required. A typical result from 9 such injections is seen in the clinical chart in Figure 5.

The performance of daily intraventricular injection in the ward is not dangerous if carried out with the strictest aseptic routine, and has been done many times by the writer without mishap. It should only be performed however, by an operator skilled in the procedure. Theoretically the greatest danger is the introduction of contaminant organisms into the cranium that may be penicillin resistant or penicillinase producers; this has never occurred in any of our cases.

The burr holes should be made well away from the cerebral motor region in case an intracerebral abscess forms along the track of the needle, leading to gliosis and cerebral scar formation and the possibility of subsequent epilepsy. This is especially important in children but may be avoided by using only frontal or parieto-occipital burr holes, and by withdrawing the brain needle on every occasion while actually injecting the penicillin solution. In babies the procedure of ventricular injection may be carried out by puncturing the lateral angles of the superior fontanel with a fine steel needle, but the writer feels that perhaps even in these cases burr holes should be employed in view of the possibility mentioned above.

SUMMARY

1 The factors controlling the passage of penicillin through the blood-brain barrier are discussed in the light of previous experience

and the results obtained by the writer in a series of cases. It is concluded that therapeutically adequate concentrations of penicillin cannot be maintained for sufficient time in the cerebrospinal fluid by systemic administration of the drug.

2 The historical features of the development of the procedure of direct introduction of penicillin into the cerebrospinal fluid are reviewed.

3 Possible complications of the procedure are discussed and shown to be avoidable and of small significance if proper care is exercised.

4 Certain clinical criteria which the writer considers to indicate repeated intraventricular administration of penicillin are enumerated and discussed.

5 The operative procedures and post-operative management of cases thus treated are described.

THE SIGNIFICANCE OF SKIN RECURRENCES FOLLOWING RADICAL MASTECTOMY

DAVID R. OLIVER, M.D. Saint Louis, Missouri and EVERETT D. SUGARBAKER, M.D.
Columbia, Missouri

RECURRENCE as related to cancer implies the persistence and eventual clinical manifestation of disease not eliminated at the time of treatment. Therefore the recurrence of breast carcinoma in the structures of the chest wall following breast removal indicates that tumor tissue, microscopic in size, was left behind at the time of operation. There has been considerable discussion regarding the influence of wide skin removal on the subsequent development of skin recurrences. However, there appears to be some confusion as to the true etiology of skin recurrences and their significance in relation to treatment and prognosis of carcinoma of the breast. It is with this aspect of the problem that this paper is primarily concerned. Twenty six cases of carcinoma of the female breast in which the patients were subjected to radical mastectomy and later developed skin recurrences form the basis of this presentation.

Since it is well recognized that the problem of breast carcinoma is intimately related to the lymphatic drainage of the breast, it is appropriate to review briefly at the outset this somewhat intricate anatomy.

Rouvière describes the cutaneous lymphatics of the mammary region as follows. In the region of the nipple and areola, the lymphatic capillaries form a dense network, the areolar network, which consists of several planes continuous with the superficial cutaneous plexus of the thoracic integument (papillary lymphatic plexus of the skin). From this network arise small lymph vessels which empty into a subdermal plexus, the subareolar lymph plexus. The subareolar plexus receives a large portion of the lymphatics from the breast and gives origin to the great afferent lymph trunks from the mammary gland proper. In the outer circumference of the areola, the subareolar plexus

becomes less dense, and its meshes enlarge to form the circumareolar plexus. This plexus merges into the same lymphatic capillary network as the other cutaneous lymphatics draining the anterior thoracic wall and presents the same lymph node connections—that is, the collecting vessels which drain the thoracic cutaneous network converge from the median line and the anteroinferior part of the thorax upon the axilla, penetrate it and empty into the external mammary group of lymph nodes, chiefly the superior group.

In addition to this principal path of collection, there are three secondary paths of drainage: (1) the supraclavicular lymph nodes, (2) collecting vessels which originate in the median portion of the anterior thoracic wall accompany the perforating rami of the internal mammary artery, transverse the pectoralis major and intercostal muscles, and finally empty into the internal mammary chain of nodes, and (3) the group of collecting vessels called by Rouvière, the anterolateral lymphatic path, which cross the midline preternally and run from the integument of one breast to the axilla of the opposite side. This third path was demonstrated by Oelsner. It provides the means by which contralateral axillary nodes may be involved independently of a new primary tumor in the opposite breast.

The cutaneous lymphatic network of the anterior thoracic wall is continuous with the cutaneous network of adjacent regions such as the abdomen, the neck, and the upper extremities. This arrangement described first by Sappey and then by Handley, was well demonstrated by the classical experiment of Kolodoy, who incised the pectoralis major muscle of one side transversely, injected carmine into the caudal portion of the muscle, and noticed that the carmine appeared in the contralateral axillary and inguinal lymph nodes and in both groups of

Fig. 1. Diagram showing the anatomical positions of the various plexuses: *a*, superficial cutaneous plexus or Sappey's subpapillary plexus; *b*, deep cutaneous plexus of Arnold; *c*, superficial fascial plexus, the chief path of lymphatic drainage from the breast and surrounding skin; *d*, vertical lymphatic trunks to the dermal papillae; *e*, deep vertical trunks to the underlying structures.

The main plexus into which the cutaneous lymph drains is the so-called superficial fascial plexus. The circumareolar plexus merges with this plexus and is thereby continuous with the cutaneous lymphatics of the entire thorax and adjoining regions. As mentioned previously continuity is evident from Kolodny's experiment, in which retrograde lymphatic flow was initiated. In the mammary region the superficial fascial plexus lies in the retromammary and deep subcutaneous tissue just superficial to the fascia of the pectoralis major muscle. Numerous small lymphatic capillaries arising in the papillae of the dermis converge forming larger vertical vessels which empty into it.

There has been considerable controversy in regard to the superficial cutaneous plexus (Sappey's subpapillary lymphatic plexus). Rouvière indicates that the areolar plexus merges with this network. Handley on the other hand was unable to demonstrate a superficial plexus in the dermis and felt that there is a complete independence of adjoining 'lymphatic areas' of the skin which he estimated to be $\frac{1}{8}$ to $\frac{1}{2}$ inch in diameter. In other words Handley's conception likened the vertical trunks draining into the fascial plexus to a forest of trees with many branches, none of them connecting with each other.

This anatomical picture is further confused by the frequent description of another lymphatic network, the deep cutaneous plexus located at the junction of the middle and deep

thirds of the dermis. The anatomical positions of these various plexuses are shown diagrammatically in Figure 1. Dermatologic pathologists are likewise divided in their ability to demonstrate either Sappey's or Arnold's cutaneous plexuses, but they are in general agreement that the most important path of drainage from the skin is by the superficial fascial plexus.

While the value of radical mastectomy established by Halsted and Willy Meyer, is unquestioned in the treatment of carcinoma of the breast there has been little agreement regarding the method of dealing with the skin. The disagreement seems to be intimately concerned with the various concepts of spread of carcinoma within and beyond the limits of the breast. These concepts are obviously related in turn to the respective interpretations of the anatomical considerations of the cutaneous lymphatics in the mammary region.

One of the early workers to study the spread of breast cancer was Handley. His classical work is probably the most often quoted but at the same time it has received widespread criticism. Handley concluded that the growth of breast cancer to the skin was chiefly by permeation into the lymphatics of the superficial fascial plexus with later extension upward into the vertical skin lymphatics to form clinically visible skin nodules. Heidenhain and Handley showed that permeation of the fascial lymphatic plexus from the primary

Fig. 2. Diagrammatic illustration of the most common sites of skin nodules. For convenience in diagramming the right side is assumed to have been the site of primary involvement in all cases.

mammary carcinoma may occur relatively early in the disease and often before the breast is demonstrably fixed to the pectoral fascia. Handley by no means denied the possibility of lymphatic embolic dissemination. In fact, he stated that the axillary and regional lymph nodes are often involved as a result of tumor emboli thus producing retrograde lymphatic flow. Handley believed that skin nodules appearing over the area where the deep fascia had been excised were simple "efflorescences without bad prognosis, but that skin recurrences over the intact fascia indicated proliferating growth and certain death. However as will be indicated later it would appear that efflorescent recurrence is either rare or without appreciably different outlook.

As a result of his studies Handley practiced and taught relatively narrow skin excision but wide peripheral dissection of the fascia and the subcutaneous level where he assumed the tumor to be permeating. Several workers notably Cheattle have taken exception to Handley's permeating theory. As evidence they have shown that sections cut serially from the infiltrative edge of the primary growth to the regions of metastatic growth will show intervening areas where no permeated lymphatics can be found. This is conclusive evidence according to these investigators, that spread is

by emboli in the lymphatics and not by permeation. Gilchrist and David in their work on carcinoma of the rectum, further emphasized evidence pointing toward spread by emboli. Handley defended his permeation theory by explaining those intervening areas which were free from permeated lymphatics to be the result of a defensive action of the invaded tissue resulting in "perilymphatic fibrosis. However Handley's major contribution has been to emphasize the importance of the superficial fascial plexus as the route by which cancer of the breast gains widespread dissemination to the skin and surrounding regions.

Willis agrees that permeation of breast carcinoma may occur upward from the fascial plexus in the manner described by Handley and may thereby produce skin nodules. However Willis, as well as Daus and Miescher places equal importance upon tumor emboli in retrograde lymphatic flow caused by blockage of regional lymph nodes and deep lymphatics. Willis also states that secondary embolic foci may serve as the origin of further permeation. In addition several references to apparently genuine case reports of hemic dissemination of breast cancer to the skin are given in Willis' book. Batson likewise, after working with ink injected material also emphasizes the fact that venules as well as lymphatics may serve as paths of dissemination to the skin. Willis concludes that skin metastases from carcinoma of the breast do not result from lymphatic permeation or emboli or hemic dissemination alone, but are in varying degree the result of all of these routes.

Stiles, writing in 1892 of his findings after using osmic acid fixation of the breast in normal and pathologic conditions showed a clear understanding of the dissemination of breast cancer. His observations led him to conclude that the efferent lymphatics of the corpus mammae of the fat around it and of the nipple areola and skin over it open either directly or indirectly into the lymphatics of the deep fascia.

Stiles denied Sappey's contention that two or three collecting lymphatic trunks leading from the subareolar plexus are the ultimate and only channels for the receipt of lymph from all parts of the breast. He was able to demonstrate clearly small foci of tumor

located in the deep lymphatics remote from the primary tumor and depending for their origin upon the arrest growth of cancerous emboli. Since the diffuse anastomoses of the lymphatic vessels of the fascial plexus between the mammary and surrounding regions were well known to Stiles, it is not surprising that he wrote at this early date of the importance of removing the retromammary tissue, axillary fat and nodes pectoral and axillary fascia, along with the breast in all cases of carcinoma. He concluded that it is impossible to predict toward which regional lymph nodes the cancer

emboli from any given point of the breast may be conveyed.

It is clear that the lymphatic drainage of the breast is in intimate relation with that of the overlying skin as well as with the skin of the surrounding regions through the rich anastomoses of the subareolar plexus into the circumareolar plexus and finally into the superficial fascial plexus. The superficial fascial plexus is of prime importance in that it serves as the largest afferent lymphatic group from the mammary gland and the skin of the entire body to the regional nodes. Cancer cells from

the primary growth in the breast readily penetrate the lymphatic vessels and may permeate them for varying distances. Emboli from these invasions are broken off and swept to the axillary lymph nodes grow there, and often completely block the cortical sinuses to further lymph drainage. In consequence, retrograde lymphatic flow may occur and because the anastomoses of the fascial plexus are so extensive, tumor emboli can be carried to areas remote from the primary tumor as, for example, to an ipsilateral inguinal lymph node. As Stiles indicated and Kolodny demonstrated it is impossible to predict how far reaching such a process may be. The emboli may lodge as small foci in the fascial lymphatics only to permeate later into the vertical skin lymphatic capillaries, or they may be swept directly into the vertical skin vessels.

It would appear therefore, that much of the recurrence of tumor in the skin originates from malignant cells present in the fascial plexus, and that these malignant cells are capable of spreading to surrounding anatomical regions. Undoubtedly some skin nodules are the result of direct permeation of the deep lymphatics and vertical spread into the cutis without the aid of embolization. Hemic dissemination probably accounts for a small percentage of skin recurrences. All of these methods of spread would appear to be operative in the production of local recurrences. To attempt to define closely the exact route in each instance is of academic interest only. The important thing to be borne in mind is that the superficial fascial plexus serves as the primary route of lymph drainage from the skin of the mammary region as well as the breast itself and because of the extensive anastomotic potentialities of this plexus combined with retrograde lymphatic flow skin recurrence by any route necessarily implies true metastases.

Another factor concerns the involvement of axillary lymph nodes by tumor. As has been indicated extensive lymph node involvement is often followed by retrograde lymphatic flow. Since the incidence of axillary metastases is extremely high in patients developing skin recurrence, it seems probable that retrograde embolization is frequently responsible for the skin recurrence.

Although there are several instances in the literature in which excision of skin recurrences near the operative scar was followed by freedom from further disease for as long as 10 to 15 years such instances are extremely uncommon and suggest the occasional inoculation of tumor cells at the time of operation. Unusual happenings of this nature probably contribute little to an understanding of the real problem.

Lewis and Rienhoff in reporting the results of radical mastectomy for carcinoma of the breast at Johns Hopkins Hospital from 1894 to 1931 consider that local recurrences represent either inoculations at the time of operation or uninterrupted tumor in the cutis that was transected at operation. They have substituted the term 'regional metastases for regional recurrences,' though this seems paradoxical considering their own interpretation of skin recurrence. The outcome of their studies, in line with the principles laid down by Halsted has been the technique of wide skin excision followed by a Thiersch graft over the operative defect. Lewis and Rienhoff conclude in their paper that 'regardless of the extensiveness of the disease, so long as it remains confined within possible operative limits, it is incumbent on the surgeon to perform the most radical and meticulous operative procedure, including a far wider excision of skin than has been customary in even the Halsted Thiersch graft procedure as performed in the majority of instances in the past, for it is only by this method that the proper amount of skin and subcutaneous tissue will be sacrificed. There alone exists the possibility of reducing local recurrences to a minimum.

Another school of thought led by Auchincloss agrees with the Halsted principles but believes that they do not go far enough, as the spread of cancer peripheral to the excised skin takes place in the tissue immediately beneath the cutis. Therefore, a more careful and painstaking dissection of the remaining skin around the excision must be made so as to leave no fat attached to the undersurface of the skin.

White and his co-workers have renewed interest in the work of Handley. White considers, as do most surgeons, that a primary closure is preferable to skin graft if it does the patient no harm. He states that a minimum

width of 15 centimeters of skin should be removed and that by liberal undercutting the flaps can usually be easily approximated without undue tension. He believes that the advocates of skin grafting have adopted an empirical attitude that is not yet supported in fact.

Though it has been rather widely implied that the incidence of postmastectomy skin recurrence is in general a reflection of the operative technique, little has been done in retrospective study of other underlying factors which might influence the later development of skin recurrence, or in consideration of whether by means of excessively wide skin removal any material gain is accomplished in increasing the long term survival of patients.

Out of 450 cases of carcinoma of the breast from the records of the Ellis Fischel State Cancer Hospital we found 26 cases of biopsy proved skin recurrence developing in or adjacent to the operative field in patients that had had radical mastectomies. It is on these 26 cases that our discussion is based. No attempt has been made to calculate percentage recurrence since in many of the 450 cases sufficient time has not elapsed for the appearance of future inevitable skin recurrences.

The average incidence of local recurrence following radical mastectomy can be obtained from a general review of the literature. Lewis and Rienhoff report a rate of 26.6 per cent in 541 patients who had careful follow up attention. In White's series of 254 patients 23.5 per cent developed local recurrence. Hoopes and McGraw report a 15 per cent local recurrence in 246 patients. Rodman reports the extremely low rate of 2.2 per cent local recurrence in 132 patients of whom 61 per cent survived for at least 5 years. It should be noted, however, that these patients were personally selected. Other contemporary writers generally report figures of 10 to 30 per cent local recurrence. It is interesting to note that prior to the initiation of the radical mastectomy operation for carcinoma of the breast surgical masters like Billroth, Czerny, Fisher and Gussenbauer reported local recurrences in 62 to 82 per cent of their patients.

In reviewing our cases we have attempted to determine what correlation exists between certain preoperatively recognized clinical find-

ings known to influence adversely the prognosis of breast carcinoma and the subsequent manifestation of recurrences. Table I shows the clinical findings and the operative sequelae.

In 4 cases (Nos. 5, 6, 14, 15) operation may be considered to have been hopeless. These patients presented initially suspected and later obvious distant metastases. Operation was performed in order that the patients might receive the benefit of the existing doubt in regard to the suspected metastatic disease. If one accepts the summation of local factors constituting inoperability as outlined by Stout and Haagensen, in 6 additional patients (Nos. 1, 3, 11, 13, 17, 18) the cancer might have been considered inoperable, bringing the total to 10. All of these patients have now died of generalized disease, pulmonary metastases being present in 8 of the 10. Of the remaining 16 patients 8 presented at least one highly unfavorable clinical sign. Ten of these 16 are dead of carcinomatosis and all of the remaining 6 patients still living have shown remote disease and may be expected to succumb to the cancer in due course of time.

It has been repeatedly shown in published reports that the incidence of local recurrence is greatly increased when axillary metastases are present (16, 17, 18, 19, 20). Warren and Tompkins have produced some interesting data on this point. They have shown that skin recurrences are three times more common when axillary nodes are invaded by tumor and that the incidence of skin recurrence increases in direct proportion to the percentage of lymph nodes involved by disease. In their series there was only a 7 per cent skin recurrence when no axillary lymph nodes were involved but a 21 per cent skin recurrence when all of the axillary nodes were invaded. They maintain that it is reasonable to suppose that patients in whom metastases have occurred to the axillary lymph nodes should also have other metastases to the skin over the chest wall, thus increasing the likelihood of recurrence in the scar. They interpret their data to suggest that local recurrences are of the nature of metastases rather than implants. In emphasis of this interpretation Warren and Tompkins note that the patients in their series who had no axillary lymph node involvement

TABLE II

No. patients	Total nodes involved	N nodes dissected	
	Per cent	Average	Range
		7	4-20
0	less than 5	20	8-20
	5-20	5	
6	20-75	14	9-25
4	75-90	20	7-27
4	100		10-26

but who developed skin recurrence (a total of 8) died of widespread metastatic cancer.

Table II gives, in rough figures, the per centage of axillary lymph nodes found to contain cancer in our patients. Only 2 of the 26 patients were free from apparent metastases to the axillary lymph nodes, as determined by examination of the operative specimen. In 1 of these patients, only 4 lymph nodes were examined, so that it cannot be definitely stated that there were no metastases. Only 2 of the 15 patients in whom 25 per cent or more of the lymph nodes were involved are still living. On the other hand 4 of 11 patients with less than 25 per cent of the axillary nodes involved are still living, though all have widespread disease.

In general our policy has been to excise as much skin as is compatible with primary closure except where other considerations such as a small breast, a large tumor or a tumor superficial in the breast or involving the skin are present. Fourteen of our patients required skin grafting and 12 had flap closure of the wound. It is not our purpose to contribute to the controversy regarding what constitutes adequate skin removal. However it is difficult to imagine what skin grafting contributed to the overall prognosis in the 14 patients in whom it was carried out or what flap closure contributed in the other 12.

The location of the skin nodules is shown diagrammatically in Figure 2. It is seen that the most common site of recurrence is along the margin of the scar or at the periphery of the grafted area. One would expect this site to be the most frequent on the basis of simple mechanical dynamics. Handley explained the

TABLE III.—TIME AVERAGES

(b) Patients living (6)	55.7 years
(c) Patients dead (20)	50.6 years

fact that recurrences are found most frequently near the site of the primary tumor on the basis of a centrifugal spread of cancer. The next most frequent site is over and parallel to the sternum. The collecting lymphatic vessels which accompany the perforating branches of the internal mammary artery undoubtedly account for most of the recurrences along the sternum. These lymphatic vessels are in direct communication with the superficial fascial lymphatic plexus. Less often involved areas are found in and near the axilla and supraclavicular regions of the same side. Several of our patients developed skin nodules in or around the axilla of the opposite side.

The averages of various time intervals relative to our series are listed in Table III.

CONCLUSIONS

While radical mastectomy has been universally adopted as the most effective method of dealing with carcinoma of the breast, the reported incidence of skin recurrence following this procedure remains at between 10 and 30 per cent. Surgeons, in an attempt to lower this incidence, have proposed many technical maneuvers and variations in procedure, usually aimed at increasingly wide skin removal. However it appears that such technical attempts at elimination of local recurrence are of little value in effecting a cure of carcinoma of the breast. Our study of the 26 patients at the Ellis Fischel Hospital who developed skin recurrences following radical mastectomy clearly shows that the tumors present in these cases were advanced and aggressive. Indeed, in 10 of the 26 patients there was evidence of such advanced disease that operation might have

been considered futile by generally accepted clinical criteria of operability

Therefore, it would appear to be a proper concept that skin recurrences indicate that not all of the carcinoma was accessible to the surgeon at operation regardless of how radical his procedure, and that the cancer was inoperable.

This concept is based upon the fact that the route of metastasis of breast carcinoma to the skin is usually by the superficial fascial lymphatic plexus with vertical growth into the skin. Permeation as proposed by Handley and embolization in retrograde lymphatic flow are probably the chief modes of metastasis the latter appearing to be the one of primary importance. When the axillary lymph nodes are uninvolved and yet skin metastases appear later it may be assumed that hemic embolization direct lymphatic permeation or independent lymphatic embolization without retrograde flow was the manner of dissemination (20) By any of these means it may be anticipated that remote metastases may also develop. Although there can be little question that recurrences may also result from direct implant of tumor cells this would seem to happen quite rarely and in all likelihood is usually associated with wide lymphatic involvement as well.

The safe amount of skin to be removed in radical mastectomies has given rise to great disagreement. Bearing in mind the lymphatic system of the breast and surrounding integument incision of the skin at a distance beyond the tumor equal to the distance permitted between the tumor and the chest wall should provide more than ample skin removal. Wide skin excision although it might conceivably diminish the clinical manifestation of skin recurrences would not in our opinion improve the 5 year survival of patients. This conclusion is borne out by careful comparison of the reports of those who regularly practice skin grafting and those who do not. If lymphatics of the superficial fascial plexus have become involved either by embolic arrest or permeation wide skin removal does not prevent recurrence

It seems reasonable to conclude that skin recurrence is but the indicator of the recrudescence of more widespread disease already clinically apparent or soon to become so. It is our opinion that treatment of the recurrence, either surgical or radiotherapeutic, adds little or nothing to patient's life expectancy.

Thus, decreasing the incidence of skin recurrence would appear to be dependent among good surgeons not on the commonly discussed variation in surgical technique but on the earlier diagnosis and surgical treatment of breast cancer and on the adherence to even narrower criteria of operability than have been previously followed. In fact it is believed by some workers (19) that patients with advanced but still technically resectable carcinomas live less long after operation than do those who are refused radical mastectomy.

THE IMMEDIATE CARE OF NERVE AND TENDON INJURIES

FEW types of injury can impose a greater handicap upon the working man or the boy or girl beginning the active years of life than a deep laceration of the palm or forearm with division of nerves and tendons. It is in these two groups, in particular that such injuries are most likely to occur. The workman handling metal plates and strips, working with glass sheets or bottles or with heavy machinery with shearing edges, the youngster at play falling with a bottle or tumbler clasped tightly in his hand or pushing his forearm through a glass door or window, the adventurous schoolboy rummaging in fascinating heaps of discarded tin cans, automobile fenders and glass containers, and the luckless individual of any age involved in an automobile accident—any one of them can confront the surgeon and at any hour with a

severe injury that taxes both his surgical judgment and his surgical skill.

As with every surgical procedure an accurate preoperative diagnosis enables the surgeon to work effectively and with assurance. No one emphasized this fact more clearly in his writings and teachings than the late Torrey Harmer of Boston or described more clearly how with a few simple tests of movement and of sensory function, and usually without removing the first aid dressing, the surgeon could recognize with certainty the division of nerves and tendons and identify which were injured and which intact.

When one is suddenly confronted with a deep wound in which the tissues are uniformly discolored with blood and in which all the anatomical structures seem to be fused into a single soft mass of dusky red, areolar tissue and blood clot, one needs both the courage and assurance that come from an exact recognition of the extent of the injury.

The prompt healing and the freedom from postoperative wound reaction and discomfort that follow operative procedures when no hematoma formation or wound infection has taken place are nowhere more essential for a successful outcome than in the case of nerve and tendon injuries. A divided nerve must heal with a minimum of fibrous tissue formation if nerve axons are to find their way into the distal segment of the divided nerve. Tendons must again glide back and forth if function is to be restored. The induration and fibrosis that follow extravasation of blood into the soft tissues and that are so pronounced in tissues in which infection has taken place can cause compression of injured nerves that results in interruption of nerve impulses, scar

formation at the site of union of divided nerves that blocks downgrowth of nerve axons and fixation of sutured tendons that makes free gliding movement difficult or impossible. The fibrous tissue formation that could conceivably strengthen the abdominal wall after closure of a hernial opening or reinforce the site of closure of a perforated bowel can make the restoration of function after the repair of nerve and tendon injuries exceedingly difficult or even impossible to accomplish.

How can one be assured of the maximum chance for success in the repair of such an injury? A number of factors must be considered but first in importance is the *time that has elapsed*. One could almost assert categorically that if the injured patient is seen promptly—within a half hour after injury has occurred and if the first aid treatment has been limited to the immediate application of a sterile bandage and a compression dressing it should be possible to convert any lacerated wound without extensive tissue loss into a clean surgical wound that can be repaired and that can be expected to heal by primary union. This possibility diminishes definitely with every half hour that elapses and after three hours one would be unwilling to attempt primary repair of divided nerves and flexor tendons. Lost blood can be replaced by transfusion; there is no compensating substitute for lost time.

Other factors in addition to the time that has elapsed should be thoughtfully considered. The possibility that bacterial contamination has been added to an open wound as a result of overzealous first aid treatment must be kept in mind. More and more, surgeons in industry and men who constantly see patients with compound wounds emphasize the importance of covering the open wound with a sterile dressing at the earliest moment, applying a compression dressing and immobilizing splint,

and avoiding any examination of the wound, any chemical applications or any effort to tie off bleeding vessels as a first aid measure. Simple compression with an elastic bandage or direct manual pressure over a sterile dressing can arrest even arterial bleeding. Rarely is a tourniquet required in first aid treatment; too often it accelerates bleeding instead of arresting it. The late Mont Reid often commented on the frequency with which bleeding from an open wound ceased when the tourniquet was removed and the part elevated.

The circumstances under which the injury was sustained deserve consideration. Clean cut wounds of clean hands, caused by sharp metal or glass and sustained indoors are least likely to be contaminated. At the opposite end of the scale are wounds from more blunt objects sustained out-of-doors, perhaps in a dirty street or in an accident on the farm. Hands and forearms covered with grease and oil are not necessarily infected; one often sees wounds of greasy hands heal kindly even though the grease has thoroughly stained the exposed tissues of the open wound.

It is hardly necessary to add that a well equipped operating room with adequate assistance from anesthetist and house staff is essential in carrying out efficiently what can be a trying and tedious surgical procedure. To attempt to repair divided nerves and tendons in unfavorable surroundings and without sufficient aid almost certainly results in failure.

The difficult emergency operation often imposes a psychological handicap on the surgeon and his assistants. It comes unexpectedly. It thrusts itself like an unwelcome visitor into a well ordered routine. Often it is difficult to postpone planned procedures and give one's undivided attention to the unanticipated problem in which time is of the essence. Here again necessity knows no choice, and the

best interests of the patient will be served if the surgeon can promptly and whole heartedly transfer his attention to the new and unexpected task.

In the operating room the preparation of the wound transformation of the contaminated wound into a clean surgical wound is one of the most important steps in the surgical treatment. Zininger, Hermann, Altmeier and their associates at the Cincinnati General Hospital have performed a splendid service for the medical profession in their excellent motion picture demonstration of how wound cleansing and preparation for repair can and should be carried out. Their demonstration has been seconded and emphasized by an excellent film on the surgical preparation of patients with compound injuries prepared by the Medical Department of the Navy. Insistence on patience, thoroughness, and avoidance of mechanical and chemical trauma emphasizes surgical principles which are everywhere accepted, and which these films illustrate so graphically. If they continue to receive the publicity and attention they deserve the standards of care will be measurably improved wherever surgical work is being done.

When wound cleansing is complete the surgeon must make the final decision as to whether immediate repair should be undertaken. If he is satisfied that the open wound has been transformed into a clean surgical wound and if it can be closed without tension there is every logical reason for immediate suture of divided nerves and tendons. If he is still in doubt it is wise to close the wound without tension and postpone the repair until healing has taken place and inflammatory reaction subsided. Repair and incomplete closure are inconsistent with one another and fail to give satisfactory results. The local use of chemotherapeutic agents favors hemorrhagic exudation and hinders rather than helps the

healing process. Surgeons for the most part agree that sulfonamides and penicillin are of very great value in preventing spreading infection but they cannot safeguard the patient if surgical principles are neglected or ignored. Too many failures in the past have demonstrated that one cannot safely extend the indications for repair and closure of compound injuries because improved chemotherapeutic agents are now available. They constitute an added safeguard but not a substitute for time tested methods.

In the operative procedure two helpful aids are available to simplify the operation. The use of a bloodless field secured with the aid of a blood pressure cuff is an important advantage always available to the surgeon operating upon the extremities. Extension of the wound of injury both above and below by incisions that do not cut across flexion creases permits adequate exposure and enables one to identify injured structures with certainty something which is exceedingly difficult to do if one begins the dissection in the uniformly discolored tissue present at the level of the injury. Gentleness in handling tissues, the use of fine non-absorbable suture material, accurate apposition of divided tendons and nerves, complete hemostasis, protection of the suture line of the divided structures with soft areolar tissue and careful closure of the fascial envelope that surrounds the structures of the forearm, that holds them in place and separates them from overlying subcutaneous tissue and skin—all are simple principles which are accepted by good surgeons everywhere and all are of great importance in achieving a satisfactory result.

The younger surgeon whose experience has been largely with military casualties, and whose surgical decisions have been guided by directives laid down as broad policies, may be perplexed at times in transferring his war ex-

periences to the problems of civilian surgery. The opportunity to see the patient promptly after injury to care for him immediately, to give him as much time as is necessary for meticulous surgical care and to follow him day by day all help to make possible procedures that could not be attempted with safety under the conditions which obtain in military surgery. The surgical skill that has been acquired in handling large numbers of cases can be of inestimable value if it is combined with a realization of the opportunities associated with individualization rather than mass treatment of surgical problems.

Alertness good surgical judgment and the willingness to undertake a difficult surgical task promptly rather than to see the patient in the morning will secure the optimum results for patients with serious nerve and tendon injuries. When one recalls how completely an individual's outlook on life can be changed by such an injury whether the patient is a workman whose livelihood depends on the function of his hand or a youngster with life stretching before him it is not too much to ask that he shall receive the most skillful aid that good surgery can bring to him.

THE BOOK SHELF

CANCER AND POLITICS

The Operation on Grover Cleveland

M G SEELIG M D F A C S St Louis Missouri

EVERY story is set off by its accompanying background. Sometimes this scenery has to be created by literary artifice in other instances, nature or circumstance supplies it. In 1893 one of the most dramatic surgical operations in American history lent color to a period that was packed with sufficient explosive tinder to alarm the best and most patriotic minds of our people. The patient was Grover Cleveland the President of the United States. The operation was the removal of his left upper jaw which was the seat of malignant disease.

Age, overwork, obesity, the attritional effect of his years in office with their influence on prognosis are not insignificant details of background but after all they constitute technical data of purely surgical significance. At the very heart of the concern of those charged with the destiny of our country in 1893 was the fact that in one pan of the balance lay the life of a man and in the other all the elements of an incipient political revolution.

Here is the picture. In November of 1892 Grover Cleveland won his second election for the Presidency of the United States over his opponent Benjamin Harrison and on March 4, 1893, took office. This was a period of exciting unrest due to the heavy exportation of gold by the United States, the suspension of free coinage of silver by India, the lack of confidence in public credit due to the shortage of gold in the treasury of the United States, the fear of a silver basis, the unwise speculation of this era and the problem of general unemployment. These various factors precipitated on June 27, 1893, a devastatingly disastrous panic. One of the first acts of President Cleveland was to call a special session of Congress for August 7, 1893, to repeal, absolutely and uncompromisingly the Sherman Act. The essential goal for driving Congress over partisan hurdles on to this repeal,

was that very "defiant frankness" and blazing indiscretion which were in reality Cleveland's powerful virtues even though construed by his foes as his faults. It was literally on the very eve of this battle that the President developed farcoma of the left superior maxilla.

On June 18, 1893, just 50 days before Congress was to meet in special session, Dr. R. M. O'Reilly, who later became Surgeon General of the United States Army, examined the President and discovered an ulcer of the left side of the hard palate, this lesion was about one and one-half centimeters in diameter, encroaching on the soft palate and the underlying bone. A portion of the lesion was excised for biopsy and was pronounced by the pathologist of the Army Medical Museum (who did not know the name of the patient) to be highly suggestive of malignancy. Dr. Joseph D. Bryant, an intimate friend of the President and a New York surgeon of renown, who was called in at the suggestion of Dr. O'Reilly, advised an immediate operation. The President accepted this counsel without qualification.

From what has already been said regarding the gravity of the economic unrest in the country, it will be appreciated readily that the diseased area in the mouth of President Cleveland, though no larger than a silver quarter, loomed on the horizon in edict proportions. The challenge of surgery had been accepted by the patient, but had the public got word of what was brewing, the consequences would have been unpredictable. Secrecy was therefore the order of the day, and as we shall see later, every circumstance connected with the incident was shrouded from both the members of Congress and the public at large.

Unfortunately, however, one newspaper man, under the by-line of "Holland" (E. J. Edwards), published in the *Philadelphia Press* of August 29, 1893, a report that the President had undergone a serious operation for the removal of some teeth

CANCER AND POLITICS

The Operation on Grover Cleveland

M G SEELIG MD F.A.C.S., St. Louis, Missouri

EVERY story is set off by its accompanying background. Sometimes this scenery has to be created by literary artifice in other instances nature or circumstance supplies it. In 1893 one of the most dramatic surgical operations in American history lent color to a period that was packed with sufficient explosive under to alarm the best and most patriotic minds of our people. The patient was Grover Cleveland the President of the United States. The operation was the removal of his left upper jaw which was the seat of malignant disease.

Age, overwork, obesity, the attritional effect of his years in office with their influence on prognosis are not insignificant details of background but after all, they constitute technical data of purely surgical significance. At the very heart of the concern of those charged with the destiny of our country in 1893 was the fact that in one pan of the balance lay the life of a man and in the other all the elements of an incipient political revolution.

Here is the picture. In November of 1892 Grover Cleveland won his second election for the Presidency of the United States over his opponent Benjamin Harrison and on March 4, 1893, took office. This was a period of exciting unrest due to the heavy exportation of gold by the United States, the suspension of free coinage of silver by India, the lack of confidence in public credit due to the shortage of gold in the treasury of the United States, the fear of a silver basis, the unwise speculation of this era and the problem of general unemployment. These various factors precipitated on June 27, 1893, a devastatingly disastrous panic. One of the first acts of President Cleveland was to call a special session of Congress for August 7, 1893, to repeal, absolutely and uncompromisingly, the Sherman Act. The essential goad for driving Congress over partisan hurdles on this repeal,

From the Department of Research of The Barnard Free Skin and Cancer Hospital, St. Louis, Missouri

was that very defiant frankness and blazing indiscretion which were in reality Cleveland's powerful virtues even though construed by his foes as his faults. It was literally on the very eve of this battle that the President developed a carcinoma of the left superior maxilla.

On June 18, 1893, just 50 days before Congress was to meet in special session, Dr. R. M. O'Reilly, who later became Surgeon General of the United States Army, examined the President and discovered an ulcer of the left side of the hard palate. This lesion was about one and one-half centimeters in diameter, encroaching on the soft palate and the underlying bone. A portion of the lesion was excised for biopsy and was pronounced by the pathologist of the Army Medical Museum (who did not know the name of the patient) to be highly suggestive of malignancy. Dr. Joseph D. Bryant, an intimate friend of the President and a New York surgeon of renown, who was called in at the suggestion of Dr. O'Reilly, advised an immediate operation. The President accepted this counsel without qualification.

From what has already been said regarding the gravity of the economic unrest in the country, it will be appreciated readily that the diseased area in the mouth of President Cleveland, though no larger than a silver quarter, loomed on the horizon in eclipse proportions. The challenge of surgery had been accepted by the patient, but had the public got word of what was brewing, the consequences would have been unpredictable. Secrecy was therefore the order of the day, and as we shall see later, every circumstance connected with the incident was shrouded from both the members of Congress and the public at large.

Unfortunately, however, one newspaper man, under the by-line of Holland (E. J. Edwards), published, in the *Philadelphia Press* of August 29, 1893, a report that the President had undergone a serious operation for the removal of some teeth

and a good deal of the bone from the upper jaw. Many of the details set down by Holland were uncannily correct. But the fact that the President had opened the special session of Congress on August 7th presenting no evidence of scar and in perfect voice tended to discount the report of Holland as more or less of a canard or at best as a gross exaggeration. The Editor of the *Philadelphia Public Ledger* Mr. L. Clarke Davis, a personal friend of Mr. Cleveland, characterized Holland's report as an infamous exploitation of a toothache and a cancer fake. Other newspapers denied that any operation had been performed. And so from the date of operation, July 1, 1893 until Dr. W. W. Keen published an authentic, play by play account of the incident, 24 years later and 9 years after Grover Cleveland's death the general public was kept in ignorance of all the facts in the case.

Before outlining the information detailed in Dr. Keen's account of the operation, the postoperative course, and the measures taken to preserve secrecy it may not be amiss to call attention to the fact that of our 33 Presidents, two have been subjects of malignant disease—Grant and Cleveland. This represents a proportion of approximately one to sixteen—a figure that is strikingly lower than the one in eight that is generally presumed to be the actuarial ratio of cancer incidence. All such figures should be taken with more than a grain of salt as anyone will realize who patiently analyzes the most authentic historic accounts of the lives and deaths of our Presidents: only to discover the difficulties in the way of establishing accurate diagnoses either of the illnesses they endured or the specific causes of death in any but a negligibly small number of them. There is no more warrant for concluding that the Presidency of the United States carries with it a partial immunity to cancer than there would be justification in assuming that the American electorate suffers from a presidential assassination complex, because in the comparatively short period of 81 years, from 1865 to 1946, we have murdered over 18 per cent of our Chief Executives.

As further evidence of the elusive value of statistics, is the fact that of the Presidents who were subjects of cancer 50 per cent recovered. Cleveland was operated upon in 1893 and died fifteen years later of cardio-vascular-renal disease, uncomplicated by anything that resembled either recurrence of the original tumor or metastasis springing from it. His various biographers refer to recurrent attacks of gastrointestinal disease but one finds nothing indicating that these attacks were in any way associated with gastrointestinal malignant disease—primary or metastatic. A

semi-official public statement, signed by his friends, Dr. Joseph D. Bryant, Dr. George R. Lockwood, and Dr. J. M. Carnochan, and published the day of his death stated that "heart failure complicated with pulmonary thrombosis and oedema, were the immediate causes of his death. This statement also reiterates the facts that Mr. Cleveland for many years had suffered from repeated attacks of gastrointestinal disease. Also that he had long standing disease of the heart and kidneys. Despite these seemingly accurate data—a copy of the official death certificate, kindly furnished me by the Department of Vital Statistics of the State of New Jersey records the duration of the President's illness as about one day. A photostatic copy of this death certificate is herewith reproduced.

The final cause of the death of President Cleveland is significant, chiefly in its bearing on the dramatic incident of the operation for the removal of the President's left upper jaw. The pre-existing cardio-vascular-renal disease must have added greatly to the concern of the surgeons. The entire episode created an explosive touch-and-go situation that not only called for the secret restoration of the health of the President, but also demanded every ounce of precaution to avoid serious postoperative complications, and to assure the resumption of his activities by the President within the short period of about six weeks before Congress met in special session. These ends must be accomplished by surgeons working on a subject who was, on any account, a poor surgical risk. It is true that the famous New York internist, Dr. E. G. Janeway after a careful physical examination, issued a clean bill of health reporting normal lungs, good pulse, little if any arteriosclerosis, and almost normal kidneys. But Dr. Keen, in discussing the hazards of anesthesia, remarks that much anxiety was due to the fact that the patient was 56 years old, very corpulent with a short thick neck, in general representing the apoplectic habitus, and harassed almost to the point of physical and nervous exhaustion by the cares of office and in particular by the unrelenting pressure of patronage and office seekers.

These details, together with those set down earlier concerning the unsettled social, economic, and political state of the Nation, furnish us all that is necessary as a background for the fateful operation, which we shall now describe. All the details embraced in this particular part of the recount rest by necessity on one source namely the story published by Dr. W. W. Keen in the *Saturday Evening Post* on the 22nd of September 1917 (page 24) Dr. Keen, a Philadelphian, who was 80

Death certificate.

years old when he wrote this article had enjoyed international pre-eminence as a surgeon for many decades. He was therefore, the logical man to serve as Dr Joseph D Bryant's consultant. Dr Bryant had as aids and additional consultants Dr Janeway the Internist, Dr Ferdinand Hasbrouck the dentist and nitrous oxide gas anesthetist Dr R. M O'Reilly ether anesthetist and Dr John Erdmann, who was Dr Bryant's assistant in private practice.

Since it seemed that secrecy could be best preserved by having the operation performed on a boat, it was decided to make use of the yacht "Onida" whose owner Mr. E. C. Benedict of New York, was a devoted and intimate friend of President Cleveland. At different times of the day and night of June 30 1893 carefully avoiding all scrutiny Doctors Janeway O'Reilly Hasbrouck Erd

mann and Keen boarded the yacht lying in New York harbor. That same night, the President with his secretary of war Daniel Lamont and Dr Bryant, boarded the yacht, which had been converted temporarily into an efficient hospital ship. Mr Benedict was also a member of the party.

On the morning of July 1 the yacht proceeded up the East River at half speed while the operation was performed. Under nitrous oxide gas anesthesia Dr Hasbrouck extracted the two upper left bicuspid teeth. Then, after Doctor Bryant had made the necessary incisions in the roof of the mouth ether was substituted for nitrous oxide gas during the rest of the operation throughout which Doctors Keen and Erdmann assisted Doctor Bryant. The entire left upper jaw was removed from the first bicuspid tooth to just beyond the last molar tooth. A small portion of the soft palate

was removed, but the orbital plate was left intact. The antrum was found to be partly filled by a gelatinous mass, grossly sarcomatous in nature and confirmed later to be sarcoma by Dr. William H. Welch, the Professor of Pathology at Johns Hopkins University. The entire operation was done within the mouth, thus avoiding an external scar as visible evidence of the performance of an operation. The skillful use of pressure packs, hot water and the galvanocautery made it possible to complete the operation with the aid of only one ligature. During the course of the operation, which lasted approximately one hour about six ounces of blood was lost. At the completion of the operation, the wound cavity was packed with gauze and the patient was returned to his bed in excellent condition. The postoperative course was uneventful, the patient's temperature never rising higher than 100 degrees F and his pulse averaging 90. Unfortunately, however, speech, "labored but intelligible" while the wound was packed, was wholly unintelligible when the packing was removed, "resembling the worst possible case of cleft palate." This defect was corrected by the New York dentist, Dr. Kasson C. Gibson, who fitted the President with an artificial jaw of vulcanized rubber.

The second day after operation the President was out of bed, and two days after that, the evening of July 5th, the yacht sailed up Buzzards Bay where the patient was transferred by launch to Gray Gables. He walked to his residence with apparent ease. A few days after this, Dr. Bryant, suspicious that a remnant of tumor tissue had escaped removal, requested Doctors Keen, Erdmann and Janeway again to board the Benedict yacht

Oneida where on July 17th, under the same secret precautions as previously all suspicious tissue was excised and the entire surface seared with the galvanocautery. Again the President was up and about on the second postoperative day.

On August 5, 1893, just twenty days after the second operation, President Cleveland arrived in Washington, D. C. in order to direct the strategy of the repeal of the Sherman Law. The law was repealed. It is generally conceded by authorities in the field of history that, had Cleveland's opponents suspected the true state of affairs concerning his physical compromise, the gravity of the consequences would have been unpredictable. Doctor Keen, in his account of the operation remarks that if knowledge of the performance of the operation had leaked out, at the time, we can only surmise and shudder over what the national and political consequences might have been.

Grover Cleveland died fifteen years, lacking a month, after the removal of his jaw. One finds no-

where in literature any credible, specific statement regarding the cause of death. As has already been noted, the death certificate is not satisfactory. There circulated a rumor a short time after Mr. Cleveland died, that his death was due to abdominal cancer. It is impossible to discover whether or not this is true or if true, whether the lesion was an independent primary growth or a metastatic lesion. None of the full length biographies clears up the question. Confronted with this dilemma, even at this late day, I inquired of Mr. Cleveland's widow, Mrs. Frances Folsom Cleveland Preston, who wrote me saying that she regretted her lack of information concerning "the doctors' side of it all." She goes on to say further in her letter that, "I never knew what it was, but it must have been the same deadly enemy internally. The doctors have all gone. No one really knows. I was close to the suffering and distress of mind and body and could be thankful when the relief came."

One participant in the dramatic incident, Dr. John F. Erdmann, who assisted Dr. Bryant is still living in the city of New York, active in the practice of surgery. I wrote him for information, and he has been kind enough to tell me that he knows that Mr. Cleveland died of intestinal obstruction but does not know whether or not the obstruction was due to a malignant growth. Dr. Erdmann feels that if the obstruction were due to a malignant growth, it must have been a second primary tumor because it developed almost fifteen years after the removal of the jaw tumor. Dr. Erdmann further states that he had been told by Dr. Bryant that Dr. Keen was called into service as consultant in order to assume responsibility in part, in the event of a fatality."

REVIEWS OF NEW BOOKS

THE second edition of Handfield Jones' *Surgery of the Hand* belongs in the library of every man who handles infections or injuries of the hand. It has been developed from a long experience in lecturing on the subject and from the need for expressing clearly and tersely the salient features of hand surgery. The author has been able to set down in minimum space the maximum of information. His approach is anatomic and physiologic; each condition is considered first from the standpoint of the structure of the area concerned from which are derived the directives for therapy. The functional significance of the hand and the various features thereof are constantly kept in the foreground and stressed. The resident and young surgeon entering his surgical practice can receive no better theme for care of wounds and infections of the hand than is given in this book.

With the tendency nowadays to rely on chemotherapeutic and antibiotic agents to compensate for errors in surgical care, the properly sobering influence of Handfield Jones' book in emphasizing principles is thoroughly in order. One cannot express this better than the author who states,

Although in penicillin we have placed in our hands a weapon of great power, let us remember it does not diminish one whit the need of early diagnosis and exact treatment if we are to achieve our real object.

As evidence of the soundness of his teaching it is observed that the section on infections has been increased by five pages by the inclusion of material on the sulfonamides and penicillin. Chapters have been added on amputations and burns, both somewhat stimulated by recent war experiences.

One might differ from the author in some things, particularly in the problem of early resumption of motion in injured and infected hands and in some phases of burn therapy. These differences hinge largely on differing concepts of the significance of rest for injured and inflamed tissues and entirely on the period during which rest should be enforced. On the question of primary tendon repair the reviewer differs somewhat on the indications for primary repair and on the feasibility of repair of tendons within their sheaths. The time limit of 8 hours within which tendon suture may be safe seems a bit too long. Four hours has seemed a safer limit. Under favorable conditions it is possible by proper enlarging incisions to expose and repair nerves and tendons as a primary operation. Repair within the digital sheaths has been shown to be feasible provided it is accomplished within 8 hours after injury provided certain prerequisites obtain and a definite technique is followed.

These criticisms do not detract from the value and significance of this book and the soundness of its

teachings. If followed by every house officer and every general surgeon the level of care of wounds and infections of the hand would be immeasurably raised.

MICHAEL L. MASON

A COMPREHENSIVE survey by Dr. Harold Thomas Hyman of the fields of general medical practice is compressed into four volumes, each of about 1000 pages.¹ These volumes are serviced by a special separately bound index. The work, intended as a complete text for the general practitioner, is divided into five sections: bodily injuries and responses to injury; disturbances of the systems of communication and co-ordination; disturbances of end organ systems; techniques of diagnosis and therapy; and prognosis. The basic material that of internal medicine is very well presented; among other fields covered are convalescence, dentistry, dermatology, emergency surgery, neurology, obstetrics and pediatrics. Incorporated is contributory information furnished by such preclinical sciences as anatomy, bacteriology, pathology, physiology and serology. The subjects of physical diagnosis, laboratory methods, clinical pathology, electrocardiography, pharmacology, and therapeutics are treated. Illustrations are profuse.

To assist in the interpretation of symptoms 310 tables of differential diagnosis by presenting symptoms and signs are included. Integration of the text is accomplished by means of an index which provides references to the separate presentations and to the tables and by means of cross references. It is therefore usually possible after taking a history and examining the patient, and after reference to the proper table, either to make a definite diagnosis or to discover what further procedures are necessary for diagnosis and thereafter to outline a program for the relief or cure of the symptoms which led the patient to seek medical advice.

This ambitious project is an encyclopedia for the general practitioner intended for reference as regards the patient rather than for straight reading. Although it is questionable whether these volumes make superfluous the use of other texts of more limited scope and doubtful whether the aim set forth can ever be completely accomplished, it must be admitted that the work is astonishingly successful. The general practitioner cannot fail to derive benefit and obtain help in his work from its use and study.

tal Surgical Problems, and surgical film exhibitions. The Friday afternoon program will include the Assembly of Initiates clinics in the hospitals and six concurrent panel discussions on respectively obstetrics, plastic surgery, neurological surgery, thoracic surgery, urology and orthopedic surgery. The concluding event of the Clinical Congress program will be the Convocation on Friday evening at 8:15 o'clock in the Grand Ballroom.

Detailed programs are listed in succeeding pages.

CLINICAL PROGRAM

The hospitals and medical schools of greater New York are co-operating in scheduling operative and nonoperative clinics, and group clinical conferences. Visiting surgeons will have excellent opportunities to attend well arranged programs of many different kinds in selected hospitals in the area. General and special demonstrations will be held on such subjects as fractures, cancer, maternal morbidity and end-result studies, clinicopathologic and x-ray conferences, newer diagnostic and therapeutic procedures, preoperative and postoperative supportive treatment, anesthesia, reconditioning and many other timely subjects. Good opportunities for studying the newer techniques and surgical procedures will be provided.

The program of each general hospital will be arranged to cover subjects in general surgery, obstetrics and gynecology, fractures, orthopedic surgery, thoracic surgery, neurosurgery, genitourinary surgery, ophthalmology, and otolaryngology.

The list of hospitals which are participating in the clinical program with the names of the hospital representatives, follows:

New York

Beckman-Downtown Hospital—Robert H. Kennedy
Bellevue Hospital

First Division—Robert Wyke

Second Division—Ernest Lampe

Third Division—W. B. Murphy

Fourth Division—Vansel Johnson

Beth Israel Hospital—Samuel Standard

Flower and Fifth Avenue Hospitals—S. T. Glasser

Golda ter Memorial Hospital—Conduct Cutler

Harlem Hospital—David Smith

Harlem Eye and Ear Hospital—C. B. Meding

Hospital for Joint Diseases—A. J. Beller

Hospital for Special Surgery—T. C. Thompson

Lenox Hill Hospital—Otto Pickhardt

Manhattan Eye, Ear and Throat Hospital—Frank Kell and

Joseph D. Kelly

Memorial Hospital for the Treatment of Cancer and Allied

Diseases—Allen O. Whipple

Metropolitan Hospital—Kenneth C. Peacock

Montefiore Hospital for Chronic Diseases and Country

Sanatorium—Arthur H. Aufses

HOSPITAL STANDARDIZATION CONFERENCE

The first formal session of the Clinical Congress will be the opening meeting of the twenty-sixth Hospital Standardization Conference. Dr. Irvn Abell of Louisville, President of the American College of Surgeons, will preside. The hospital conferences will continue on Monday afternoon, with sessions following on Tuesday, Wednesday and Thursday mornings, afternoons and evenings.

Hospital administrators, members of governing boards, medical staff members, heads of the various hospital departments and their personnel, nurses, dietitians, medical records librarians, and many other persons directly concerned about hospital progress, will be interested in the discussions of current hospital problems.

The Monday afternoon session will be devoted to a panel discussion on current problems in medical service in hospitals. Tuesday morning to improvement in food service in hospitals. Tuesday afternoon to improvement in nursing service in hospitals. Tuesday evening to a joint session for hospital trustees, medical staff officers, and administrators. Wednesday morning to discussion of personnel and public relations. Wednesday afternoon to a joint session with the American Association of Medical Record Librarians on improving medical records. Wednesday evening to a

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS

on trends in hospital administration and al hospital problems Thursday morning to a on special problems Thursday afternoon to a ad table conference on problems of the small ital in meeting the standards of the American lege of Surgeons and to a symposium on Grad e Training in Surgery and Thursday evening a special conference on the point rating system. Detailed programs appear on succeeding pages.

ANNUAL MEETING

The annual meeting of the Governors and Fel ws will be held on Thursday afternoon at 1:45 There will be election of officers and governors. The annual meeting affords the Fellows of the College an opportunity to hear reports of officials on the work of the organization and to broaden their knowledge of the methods, and their effect iveness, which are used to raise the professional and ethical standards of surgery and to promote good hospital care and general improvement in the practice of medicine. Each Fellow has a per sonal part in this work and may extend the influ ence of the College materially in his local com munity and wherever his contacts extend. Hos pital Standardization particularly offers him wide opportunity to provide better medical care for patients in the hospital in which he works through continuous progress in applying the principles of the Minimum Standard which insure the best care of the patient.

Every Fellow will be interested in the reports which will be presented on the following subjects finances Hospital Standardization Graduate Training in Surgery Medical Motion Pictures Publications Public Relations Library and Lat erary Research the work of the state and provin cial credentials committees committees on appli cant, and the Committee on History Reviews Sectional Meetings, 1947 and the Department of Clinical Research including cancer clinics and cancer detection centers, the Committee on Can cer Medical Service in Industry and the Com mittee on Fractures and other Traumas. Dr Abell, Chairman of the Board of Regents, will re port on administration of the College and Dr Arthur W. Allen will discuss the obligations and opportunities of the Fellows.

MEDICAL MOTION PICTURES

The latest available films demonstrating surgi cal procedures and related subjects will be shown in the medical motion picture exhibits which will be held daily in The Waldorf Astoria. Motion pic tures are a much appreciated feature of the Clin ical Congress. Many new pictures on varied sub

jects are being received by the American College of Surgeons for review. Both sound and silent colored films will be shown during the Congress all of which will have been approved by the Com mittee on Medical Motion Pictures.

There will also be shown the first of a series of films which are being produced by the College under a grant from the Johnson & Johnson Re search Foundation. The film is entitled "Anoma lies of the Bile Ducts and Blood Vessels. Structures of the Common Duct," a teaching film of which Dr. Warren H. Cole of Chicago is the author. It is contemplated that there will also be completed in advance of the Clinical Congress at least one additional film which is being produced by the College under the expanded program.

ADVANCE REGISTRATION

The hospitals and medical schools of New York afford accommodations for a large number of visiting surgeons. However, in order to insure against overcrowding attendance at the Congress will be limited to the number that can be accom modated at the clinics and meetings. It is there fore expected that surgeons who wish to attend the Congress will register in advance.

Because of greatly increased costs and expenses to which the College will be subjected this year in connection with its New York Clinical Congress the Board of Regents has found it necessary to require a registration fee of \$5.00 for Fellows and for endorsed Junior Candidates. Non Fellows attending as invited guests of the College will pay a fee of \$10.00. No fee will be required of initiates of the class of 1947.

The registration desk will be open from 3:00 to 9:00 p.m. on Sunday, September 7, in order to permit surgeons to obtain tickets for the Monday clinics. A new plan is to be adopted in New York of distributing clinic tickets on the day prior to the clinics, from 9:00 a.m. to 5 p.m. Any remain ing tickets will be available at 7:00 a.m. the same day on which the clinics are held.

TECHNICAL AND SCIENTIFIC EXHIBITION

The technical exhibit, together with the registra tion and clinic ticket bureaus, will be located in the Basilidon Room, Jade Room, and Astor Gallery all on the third floor of the hotel. Leading manufacturers of surgical instruments, x-ray apparatus, sterilizers, operating room lights, ligatures, dressings, hospital apparatus and supplies of all kinds, and pharmaceuticals and publishers of medical books will be represented. The techni cal exhibits will demonstrate many of the new features learned from our experience in the war.

GENERAL ASSEMBLY

JOINT SESSION—SURGEONS AND HOSPITAL REPRESENTATIVES

Monday 10.00 a.m.—12 30 p.m.—Grand Ballroom—The Waldorf Astoria

IRVIN ABELL, M.D., Louisville President American College of Surgeons, Presiding.
 Welcome from the Mayor and the Hospitals of New York. EDWARD M. BERNHEIMER, M.D. New York, Commissioner Department of Hospitals, City of New York.
 Greetings from the American Hospital Association. JOHN H. HAYES, New York President.
 Greetings from the Canadian Hospital Council. HARVEY AGNEW, M.D. Toronto, Secretary.
 Summary of College Activities as Related to Hospitals for Past Year. IRVIN ABELL, M.D. Chairman, Board of Regents.
 Need for Efficient Medical Staff Organization and Control of the Professional Work of the Hospital. HAROLD L. FOSS, Danville, Pennsylvania, Surgeon in Chief, Gelsinger Memorial Hospital.
 Better Hospital Facilities for Rural Patients—Plans to Integrate Small General Hospitals with Nearest Institutions Incorporating Specialized Services. GRAHAM L. DAVIS, Battle Creek Hospital Director.
 W. K. Kellogg Foundation, President Elect American Hospital Association.
 The New Era in Personnel Relations and its Meaning for Hospitals. BRIGADIER GENERAL ROBERT W. JOHNSON, New Brunswick, Chairman, Board of Trustees, Johnson & Johnson.
 The Potentialities of the Medical Motion Picture for Teaching Purposes. WARREN H. COLE, M.D., Chicago, Professor of Surgery and Head of the Department of Medicine, University of Illinois College of Medicine in collaboration with TOM JONES, Chicago, Professor Medical Illustration, University of Illinois College of Medicine.
 Showing: Anomalies of the Bile Ducts and Blood Vessels. Strictures of the Common Duct."

PRESIDENTIAL MEETING

Monday 8 15 10 30 p.m.—Grand Ballroom The Waldorf Astoria

IRVIN ABELL, M.D. Louisville President American College of Surgeons, Presiding.
 Processional—Officers, Regents and Distinguished Guests.
 Address of Welcome. HOWARD A. PATTERSON, M.D. New York, Chairman, Committee on Arrangements.
 Introduction of Distinguished Guests. ARTHUR W. ALLEN, M.D. Boston, Vice Chairman, Board of Regents.
 Address of the Retiring President. The Spirit of Surgery. IRVIN ABELL, M.D. Louisville.
 Inauguration of Officers.
 Presented by LELAND S. MCKITTRICK, M.D. Boston, Retiring First Vice President.
 President. ARTHUR W. ALLEN, M.D. Boston.
 First Vice President. THOMAS E. JONES, M.D. Cleveland.
 Second Vice President. GORDON B. NEW, M.D. Rochester, Minnesota.
 The Second Martin Memorial Lecture. The Qualifications of the Surgeon and the Cancer Problem. ALLEN O. WHITFIELD, M.D. D.Sc. New York, Clinical Director, Memorial Hospital, Emeritus, Valentine Mott.
 Professor of Surgery, Columbia University College of Physicians and Surgeons.
 Recessional.

CONVOCATION

Friday 8 15-10.30 p.m.—Grand Ballroom The Waldorf Astoria

ARTHUR W. ALLEN, M.D. Boston, President, American College of Surgeons, Presiding.
 Processional. Initiates, Officers, Regents, and Distinguished Guests.
 Presentation of Initiates for Fellowship. IRVIN ABELL, M.D. Louisville, Chairman, Board of Regents.
 Fellowship Pledge. Recital by Initiates.
 Conferring of Fellowships by the President. ARTHUR W. ALLEN, M.D. Boston.
 Conferring of Honorary Fellowships. The President.
 Fellowship Address. Liberal Medical Education. ANDREW C. IVY, M.D. Chicago, Vice President, University of Illinois, in charge of Chicago Professional Colleges, and Distinguished Professor of Physiology.
 Recessional.
 Reception by the Officers and Regents for the Initiates and Fellows.

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS

ASSEMBLY OF INITIATES

Friday 1 45-3.00 p.m.

IRVIN ABELL, M.D., Louisville Chairman of the Board of Regents Presiding
The Program of the American College of Surgeons Hospital Standardization Sectional Meetings, Medical Motion Pictures, Library and Literary Research, Graduate Training in Surgery MALCOLM T. MAC
EACHERN, M.D., Chicago Associate Director and Chairman of the Administrative Board
Fellowship in the American College of Surgeons. IRVIN ABELL, M.D., Louisville

Chicago Assistant Director
Qualifications for Fellowship H. P. SAUNDERS, M.D., Chicago Assistant Director

EVENING SCIENTIFIC SESSIONS

GENERAL SURGERY

Tuesday 8 00-10 30 p.m.

Symposium on The Proper Use of Blood and Blood Plasma
A Permanent Red Cross Transfusion Service G. FOARD MCGINNIS, M.D. Washington.
Blood Bank Organization. PAUL I. HOKWORTH, M.D. Cincinnati
Reactions to Blood Transfusion and the Rh Factor LOUIS K. DIAMOND, M.D., Boston.
The Use of Blood and Plasma in Surgery DALLAS B. PHEMISTER, M.D. Chicago

Wednesday 8 00-10 30 p.m.

Fracture Oration. FRANK D. DICKSON, M.D., Kansas City

Symposium on Nutritional Requirements in Surgery

Proper Employment of Oral Feeding EVERETT I. EVANS, M.D., Richmond.
Parenteral Feeding ROBERT ELMAN, M.D., St. Louis.
The Importance of Adequate Supply of Blood and Nourishment for Wound Healing S. CLAMP LYONS,
M.D. New Orleans.

Thursday 8 00-10 30 p.m.

Symposium on Hypertension

Fundamental Physiological Considerations PETER HEDENBECKER, M.D. St. Louis.
Indications for Surgery in the Treatment of Hypertension. THOMAS FREDLEY, M.D. New Orleans.
Surgical Procedures in the Treatment of Hypertension. ROBTNOLD H. SMITHWICK, M.D. Boston.
End Results in the Treatment of Hypertension. CYRUS C. STURGIS, M.D. Ann Arbor

OPHTHALMOLOGY

Tuesday 8 00-10 30 p.m.

Epithelial Downgrowth Following Cataract Operation. MILTON L. BERLINER, M.D. New York.
Local Anesthesia in Ophthalmology WALTER S. ATKINSON, M.D. Watertown New York.
Operative Treatment of Vertical Tropia BRITAIN F. PAYNE, M.D. New York.
Prevention and Management of Operative Complications During Cataract Extraction JACK S. GUYTON
M.D., Baltimore.

Thursday 8 00-10 30 p.m.

Prevention of Infection in Eye Surgery M. HAYWARD POST, M.D., St. Louis
Glaucoma Following Cataract Extraction. WILLIAM C. OWENS, M.D. Baltimore.
Retinal Detachment. HARVEY E. THORPE, M.D. Pittsburgh
The Difficult Cataract Extraction. R. TOWNLEY PATON, M.D. New York.

OTORHINOLARYNGOLOGY

Tuesday 8 00-10 00 p.m.

Symposium on Bronchiectasis

Relationship of Bronchiectasis to Sinusitis. ROBERT L. GOODALE, M.D. Boston.
The Surgical Aspects of Bronchiectasis. ALTON OCHNER, M.D. New Orleans.
The Use of Bronchoscopy in Bronchiectasis. FLETCHER D. WOODWARD, M.D. Charlottesville.

Thursday 8:00-10:30 p.m.

Symposium on Management of Carcinoma of the Larynx

Treatment by Laryngofissure. CHEVALIER L. JACKSON M.D. Philadelphia.

Laryngectomy. LOUIS H. CLIFF M.D. Philadelphia.

Management of Carcinoma of the Larynx with Metastatic Involvement of the Neck. HENRY B. OSTON, M.D. Newark.

COMBINED SESSION ON OPHTHALMOLOGY-OTORHINOLARYNGOLOGY

Wednesday 8:00-10:30 p.m.

Blood Supply of Eye and Sinuses. OSCAR V. BATSON M.D. Philadelphia.

Dacryocystorhinostomy. HAROLD GIFFORD, Jr. M.D. Omaha.

Relation of the Nasal Accessory Sinuses to Eye Diseases. EDWARD A. LOOPER, M.D. Baltimore.

Ophthalmoneurologic Symptoms of Nasopharyngeal Tumors. FRANK B. WALSH M.D. Baltimore.

FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

Tuesday through Friday 8:30 a.m. to 12:30 p.m. - The Waldorf Astoria

Presentation of the results of clinical and experimental research on problems related to general surgery and the surgical specialties which are being currently conducted in many medical schools, clinics, and hospitals.

Tuesday September 9 8:30 a.m. 12:30 p.m.

Gastric Surgery. Grand Ballroom

Wound Healing. Plastic Surgery and Infections. Serf Room

Wednesday September 10 8:30 a.m. 12:30 p.m.

Surgery of the Small and Large Bowel. Grand Ballroom

Protein, Fluid and Electrolyte Balance. Serf Room

Thursday September 11 8:30 a.m. - 12:30 p.m.

Gall bladder, Pancreas and Peritoneum. Grand Ballroom

Surgery of the Heart and Blood Vessels. Hedgewood Room

Friday September 12 8:30 a.m. 12:30 p.m.

Thoracic Surgery. Anesthesia and Thyroid. Grand Ballroom

Neurosurgery. Tumors, and Urology. Serf Room

SYMPOSIUM ON CANCER CLINICS AND CANCER DETECTION CENTERS

Tuesday 3:00-5:00 p.m.

GRANTLEY W. TAYLOR M.D. Boston. Chairman. Cancer Committee. American College of Surgeons, presiding.

Early Diagnosis of Carcinoma of Stomach. FORDYCE B. ST. JOHN M.D. PAUL C. SWENSON M.D. HAROLD D. HARVEY M.D. New York.

Experience with the Chicago Cancer Detection Center. AUGUSTA WEBSTER, M.D. Chicago.

The U.S.P.H.S. Cancer Control Program. AUSTIN V. DIEBERT M.D. Bethesda.

Utilization of Cancer Clinics for Teaching Purposes

For Undergraduates and Interns in a University Clinic. MAX TAFFEL, M.D. New Haven.

For Members of the Hospital Staff in a Clinic Not Affiliated with a University. WILLIAM R. LAIRD M.D. Montgomery West Virginia.

Utilization of Cancer Records from Clinics and Hospitals. FRANK E. ADAIR, M.D. New York.

SYMPOSIUM ON CANCER

Wednesday 3:00-5:00 p.m.

GRANTLEY W. TAYLOR M.D. Boston. Chairman. Cancer Committee. American College of Surgeons, Presiding.

Surgical Treatment of Carcinoma of the Lung. MICHAEL E. DEBAKEY M.D. New Orleans.

Tumors of the Testis. ROBERT A. MOORE M.D. St. Louis.

Biological Differentiation of Benign and Malignant Tumors. HARRY S. N. GREENE, M.D. New Haven.

Isotopes in Surgical Research. FRANCIS D. MOORE M.D. Boston.

Prognosis in Carcinoma of the Bowel. R. KENNEDY GILCHRIST M.D. Chicago.

Anterior Resection of Carcinoma of the Colon and Rectum. OWEN H. WANGENSTEIN M.D. Minneapolis.

PANEL DISCUSSIONS

GENERAL SURGERY

Monday 1:30-3:00 p.m.

Surgery of Pulmonary Infections

Moderator EVARTS A. GRAHAM, M.D., St. Louis.

Collaborators BRIAN B. BLADES, M.D. Washington RICHARD H. OVERHOLT, M.D. Brookline Massachusetts HAROLD NEUFOR, M.D. New York.

Monday 3:30-5:00 p.m.

Pancreatitis

Moderator MIMS GAGE, M.D. New Orleans.

Collaborators JOHN M. VAUGHN, M.D. Rochester Minnesota HORACE J. MCCORMICK, M.D., San Francisco.

Tuesday 1:30-3:00 p.m.

Surgery of the Spleen

Moderator ALLEN O. WHIFFLE, M.D., New York.

Collaborators GEORGE M. CURTIS, M.D. Columbus ARTHUR H. BLAKEMORE, M.D. New York ROBERT H. E. ELLIOTT, M.D. New York LOUIS M. ROUSSELOT, M.D. New York.

Tuesday 3:30-5:00 p.m.

Jaundice

Moderator CHARLES B. PUESTOW, M.D. Chicago.

Collaborators I. S. RAVDIN, M.D. Philadelphia JAMES T. PRIESTLY, M.D., Rochester Minnesota ROSCOE R. GRAHAM, M.D. Toronto.

Wednesday 1:30-3:00 p.m.

Gastric Surgery

Moderator HOWARD K. GRAY, M.D., Rochester Minnesota.

Collaborators GEORGE T. PAGE, M.D. New York WARREN H. COLE, M.D., Chicago LELAND S. MCKITTRICK, M.D. Boston.

Wednesday 3:30-5:00 p.m.

Use of Antibiotic Agents and Chemotherapy in Surgery

Moderator JOHN S. LOCKWOOD, M.D., New York.

Collaborators FRANK L. MILENEY, M.D., New York C. PHILLIP MILLER, M.D. Chicago, HAROLD A. ZINTEL, M.D., Philadelphia MAJOR EDWIN J. POLASKI, M.C., Fort Sam Houston, Texas.

Thursday 3:30-5:00 p.m.

Surgery of the Hand

Moderator HENRY C. MARBLE, M.D., Boston.

Collaborators HARVEY S. ALLEN, M.D., Chicago LAURIE H. MCKIM, M.D. Montreal J. HAROLD COUCH, M.D. Toronto.

UROLOGY

Friday 1:30-4:30 p.m.

Moderator CHARLES C. HIGGINS, M.D. Cleveland.

Treatment of Carcinoma of the Bladder

Collaborators HUGH J. JEWETT, M.D. Baltimore ARCHIE L. DEAN, M.D. New York EDWARD N. COOK, M.D. Rochester Minnesota.

Management of Renal Lithiasis

Collaborators GEORGE F. CAHILL, M.D. New York LINWOOD D. KEYSER, M.D. Roanoke RICHARD W. SATTERTHWAITE, M.D. Battle Creek.

ORTHOPEDIC SURGERY

Moderator PAUL B. MAGNUSON, M.D. Washington.

Problem of Fractures of the Neck of the Femur

Collaborators KELLOGG SPEED, M.D. Chicago RUDOLPH S. REICH, M.D. Cleveland PAUL C. COLOVA, M.D. Philadelphia.

Indications and Operative Technique for Lumbosacral Fusion of the Spine

Collaborators GUY A. CALDWELL, M.D. New Orleans DAVID M. BOSWORTH, M.D. New York MARK B. COVENTRY, M.D. Rochester Minnesota.

GYNECOLOGY AND OBSTETRICS

Moderator J. MASON HUNDLEY, JR. M.D. Baltimore

Changes in the Urinary System Engendered by Gynecological and Obstetrical Conditions

Collaborators HOUSTON SPENCER EVERETT M.D. Baltimore WILLIAM E. STUDDIFORD JR. M.D.

New York R. GORDON DOUGLAS M.D., New York.

Modern Trends in the Treatment of Malignancies of the Female Genitalia

Collaborators NELSON B. SACKETT M.D. New York ROBERT A. ROSS, M.D. Durham, William P. HEALY M.D. New York.

NEUROLOGICAL SURGERY

Late Results of Compound Craniocerebral Injuries

Moderator A. EARL WALKER M.D. Chicago.

Collaborators JAMES C. WHITE M.D. Boston CORN. PILCHER, M.D. Nashville MICHAEL SCOTT M.D. Philadelphia.

Surgical Aspects of Vascular Disorders of the Brain

Moderator JAMES L. POPPEN M.D. Boston.

Collaborators WALLACE B. HANBY, M.D. Buffalo WINCHELL MCK. CRAIG, M.D. Rochester W. JAMES GARDNER, M.D. Cleveland

THORACIC SURGERY

Moderator STUART W. HARRINGTON M.D. Rochester Minnesota.

Surgery of the Esophagus

Collaborators HERMAN J. MOERSCH M.D. Rochester Minnesota RICHARD H. SWEET M.D. Boston CARL EGGER, M.D., New York ORVAR SWENSON M.D. Boston.

Tumors of the Lung: Benign and Malignant

Collaborators (Same as above)

PLASTIC SURGERY

Moderator WILLIAM G. HANCK M.D. Atlanta.

Repair of Surface Defects of the Extremities

Collaborators TRUMAN G. BLOCKER JR. M.D. Galveston FRANK McDOWELL, M.D. St. Louis W. BRANDON MACOMBER M.D. Albany

Major Facial Defects

Collaborators BRADFORD CAMMOM M.D. Boston W. BOWDOEN DAVIS, M.D. Baltimore CARL E. LINCHER M.D. St. Louis MAJOR ANDREW M. MOORE, M.C. Phoenixville.

OPHTHALMOLOGY

Tuesday 9:00-10:30 a.m.

Surgery of Extracocular Muscles

Moderator HAROLD W. BROWN M.D., New York.

Collaborators RUDOLF AXELI M.D. New York WALTER H. FINK, M.D. Minneapolis RICHARD G. SCHERER, St. Louis.

Wednesday 9:00-10:30 a.m.

Surgery of Glaucoma

Moderator C. S. O'BRIEN M.D. Iowa City

Collaborators P. ROSS McDONALD, M.D. Philadelphia JOHN S. MCGAVIC, M.D., Bryn Mawr WILLIS S. KNIGHTON M.D. New York.

Thursday 9:00-10:30 a.m.

Angiospastic Ocular Lesions

Moderator FRANK D. CARROLL, M.D. New York.

Collaborators WALTER F. DUGGAN, M.D. Utica HERMAN ELWYN M.D. New York HENRY P. WAGENER, M.D. Rochester Minnesota.

OTORHINOLARYNGOLOGY

Tuesday 10:45 a.m.-12:15 p.m.

The Use of Antibiotics in Ear, Nose and Throat Surgery

Moderator CHESTER S. KEEFER M.D., Boston.

Collaborators WESTLEY M. HUNT M.D. New York FREDERICK T. HILL, M.D. Waterville, Maine LEIGHTON F. JOHNSON M.D. Boston.

Wednesday 2:00-5:00 p.m.—Sert Room
First Floor—The Waldorf Astoria

Conducted by ROBERT C. BURKE, M.D., Philadelphia, Director of Hospitals, University of Pennsylvania, Dean, Graduate School of Medicine.
A Message from the President of the American Association of Medical Record Librarians. EDNA C. BLACK, R.R.L., New Haven, Medical Record Librarian, Grace Unit of the Grace New Haven Community Hospital, President of the American Association of Medical Record Librarians.
The Present Status of Training Medical Record Librarians Through—
(a) Approved Schools. EDNA K. HOFFMAN, R.R.L., Chicago, Director, School for Medical Record Librarians, Wesley Memorial Hospital, Director Program in Medical Record Library Science, Northwestern University.

(b) In-Service Training Institute. MARGARET C. TAYLOR, R.R.L., Chicago, Field Instructor Extension Course, American Association of Medical Librarians.
The Proper Approach to the Maintaining of Adequate Medical Records. MARGARET DOBBS, M.D., Richmond, Assistant Director, Hospital Division, and Associate Professor of Hospital Administration, Medical College of Virginia School of Medicine.
The Responsibility of the Medical Staff of the Hospital in Maintaining Good Medical Records. MALCOLM T. MACFARLANE, M.D., Chicago, Associate Director, American College of Surgeons.
Impressions of the Field Representative of the American College of Surgeons in regard to Maintaining Adequate Medical Records. REAR ADMIRAL LUCIUS W. JOHNSON, San Diego, Assistant, Hospital Department, Assigned to Pacific Region.
Question and Answer Period. Conducted by ROBERT C. BURKE, M.D., Chairman.

A FORUM ON TRENDS IN HOSPITAL ADMINISTRATION NEW IDEAS AND PROCEDURES AND SPECIAL HOSPITAL PROBLEMS

Wednesday 8:00-10:30 p.m.—Sert Room—

First Floor—The Waldorf Astoria

Conducted by FRANK R. BRADLEY, M.D., St. Louis; Director Barnes Hospital, President, American College of Hospital Administrators.

Opportunity has been given to the graduates and administrative interns of the various Universities now offering

courses in hospital administration to present summary transcripts of new ideas and trends in hospital work, including planning and construction, improved equipment, new procedures and techniques, administrative problems, personnel management, public relations and other phases of hospital administration. From the totals of transcripts presented ten ten-minute presentations will be selected for discussion at this session.

FORUM ON SPECIAL PROBLEMS

Thursday 9:30 a.m.—12:30 p.m.—Sert Room—

First Floor—The Waldorf Astoria

Coordinator: ROBERT C. BUCKLEY, M.D., Philadelphia, Director of Hospitals, University of Pennsylvania, Dean Graduate School of Medicine

Topics for Discussion

The Modern Hospital—a Complete Synchronized Entity
New Developments in Each Group of Departments that Provide Unified Service to the Patient.

What Has Been Done to Meet the Present Acute Bed Shortage?

Present Status of Volunteer Workers in Hospitals.
Hospital Trustees, Members of the Medical Staff, Nursing Executives and Administrators Must Cooperate in Better Nursing Relations.

Are We Making Progress in the Care of the Chronically Ill?

Hospitals and the Cancer Problem—Cancer Clinics and Cancer Detection Centers.

Newer Services for the Modern Hospital—Physical Medicine and Geriatrics.

Planned Convalescence and Its Place in the Community
Adjusting Hospital Service to Medical Progress.

Interdepartmental Relations of the Pharmacy: How to Enhance Its Value and Appreciation by other Departments in the Hospital.

The Enlarging Educational Responsibilities of the Hospital.

Proper Use of the Medical Library

Incentives to Hold Employees—Including Retirement Plans.

ROUND TABLE CONFERENCE—SPECIAL PROBLEMS OF THE SMALL HOSPITAL IN MEETING THE STANDARDS OF THE AMERICAN COLLEGE OF SURGEONS

Thursday 2:00-5:00 p.m.—Sert Room—

First Floor—The Waldorf Astoria

Conducted by HARVEY AOKER, M.D., Toronto Secretary Canadian Hospital Council, Editor of *Canadian Hospitals*.

Topics for Discussion

Medical Staff Organization

Clinical Laboratory

X-ray Service

Medical Records

Nursing Service

Food Service

Pharmacy Service

Personnel Management

Public Relations

Care of Emergencies

EVA H. ERICKSON, M.H.A., Olean, New York; Super-Intendent, Olean General Hospital.

ELOISE B. FURUTAKA, M.H.A., Syracuse; Administrative Assistant, Syracuse Memorial Hospital.

WILLIAM G. ILLIEN, Whit Plains, New York; Administrator, White Plains Hospital Association.

GEORGE PRICE, Philadelphia; Administrator, Jewish Hospital.

MARSHALL L. PICKENS, Charlotte; Assistant Secretary, The Duke Endowment.

WILLIAM P. SLOVER, Manchester, Connecticut; Super-Intendent, Manchester Memorial Hospital.

ISABELLA N. WILLIAMS, Norwich, New York; Administrator, Chenango Memorial Hospital.

ROBERT G. WENTWORTH, Alexandria, Virginia; Administrator, Alexandria Hospital, Vice-President, The Hospital Council of the National Capital Area, Washington, D.C.

E. W. WILLIAMSON, M.D., Chicago; Assistant Director, American College of Surgeons.

SPECIAL CONFERENCE ON THE POINT RATING SYSTEM

Thursday 8:00-10:00 p.m.—Sert Room—

First Floor—The Waldorf Astoria

A Special Conference on the Point Rating System for Hospitals with Particular Discussion of Evaluation and Rating of Hospitals under this System.

Conducted by HARVEY G. FAIRER, M.H.A., M.D., Chicago;

Assistant, Hospital Department, American College of Surgeons.

Collaborators.

HARVEY AOKER, M.D., Toronto; Secretary Canadian Hospital Council, Editor *Canadian Hospitals*.

MALCOLM T. MACFARLANE, M.D., Chicago; Associate Director, American College of Surgeons.

PRELIMINARY CLINICAL PROGRAM

CLINICS IN NEW YORK HOSPITALS

Monday

BELLEVUE HOSPITAL

- 9:00-3:30. *Radiology* Permanent Exhibit, Monday through Friday Nonoperative Clinics. IRA I. KAPLAN and STAFF
- The Radiologic Treatment of Benign and Malignant Superficial Lesions. Irradiation as an Adjunct to Surgery. (1 and K Bldg., Ground FL—Capacity 15)
- The Place of Irradiation in the Treatment of Carcinoma of the Breast. (Same Rm.)
- A New Approach to the Treatment of Gastro Intestinal Malignancies by Radiation. (Same Rm.)
- Treatment of Carcinoma of the Cervix. (Same Rm.)
- Radiation Therapy as an Adjunct Method of Treatment in Genito Urinary Neoplasms. (Same Rm.)
- 9:00-4:00. *Röntgenology* Permanent Exhibit, Monday through Friday Nonoperative Clinics Röntgen Demonstrations of Surgical Disease
- Surgical Lesions of the Small Bowel Roentgenologically Considered. J. BUCKSTEIN (A. Ray Dept. I and K Bldg., Ground FL—Capacity 15)
- Surgical Problems of the Chest. PHILIP STRAU. (Same Rm.)
- Diagnostic Problems in Oesophagus Disease. M. ZURROW (Same Rm.)
- Diagnosis of Renal Surgical Disease. H. ZUCKERMAN (Same Rm.)
- Interesting Neuro-Surgical Cases. LEWIS J. FRIEDMAN and HERBERT LOEWEN. (Same Rm.)

BELLEVUE HOSPITAL—FOURTH (NEW YORK UNIVERSITY) SURGICAL DIVISION

- 1:30-3:30. *Surgery Specialties* (Operating Rooms K 5 and K-6). (Capacity of each operating room 5)
- Children's Surgery—Hernia. PHILIP ALLAN (Operating Room A)
- Children's Surgery—Chest. CHARLES W. LESTER (Operating Room B)
- Maxillofacial Surgery—Surgical Correction of Prognathism of the Mandible. LEO WINTER (Operating Room C)
- Orthopedic Surgical Clinic. ARTHUR KRIDA, JOHN McCULLY (Bone Room K-6)

BETH ISRAEL HOSPITAL

- 1:00-5:00. *Ophthalmology* Operative Clinic Clinical Demonstration of Endoscopic Treatment. MAX SOM and STAFF (E-N T. O.R. 12th Fl.—Capacity 6)
- Nonoperative Clinic on Results. MAX SOM and STAFF (Auditorium—Capacity 300)
- 1:00-5:00. *Ophthalmology* Nonoperative Clinic. EDWARD B. GARDNER and STAFF (3rd Fl. Classroom—Capacity 6)

FLOWER AND FIFTH AVENUE HOSPITALS

- 1:00-4:00. *Neurosurgery* Nonoperative Clinic "Slipped Disc" Operation and End Results. THOMAS I. HOEN (Auditorium, 106th St. Entrance—Capacity 300)
- 4:00-5:00. *Thoracic Surgery* Nonoperative Clinic: Trauma to Neck Involving the Mediastinum—or—Mediastinal Tumors. MILTON J. LLOYD. (Same Rm.)

HARLEM HOSPITAL

- 1:00-5:00. *Plastic Surgery* Nonoperative Clinic Symposium on Burns and Plastic Surgery. F. X. TOROWITZ, A. TAYLOR, A. GARNER and STAFF (Conference Rm. 5th Fl. Women's Pavilion—Capacity 100)

HOSPITAL FOR JOINT DISEASES

- 9:00-12:00. *Orthopedic Surgery* Operative Clinic Tendon Transplantation on the Hand. Transpositional Osteotomy at the Hip. LEO MAYER, HENRY MILLER (Surg. Amphitheater—Capacity 50)
- Follow up Demonstration
1. Result of Hallux Valgus Operation. PAUL LAPIDUS. (Prof. Serv. Bldg. Lecture Rm.—Capacity 60)
 2. (a) Transplantation of Extensor Carpi Ulnaris Tendon to Give Abduction of the Thumb (b) Meniscectomy of the Temporomandibular Joint (c) Fracture of Viphoid Viphoidectomy (d) Osteotomy Fusion of Hip. MICHAEL BURMAN (Same Rm.)
 3. (a) Slipping of the Femoral Epiphysis and Results by the Use of Internal Rotation Brace (b) Result of Osteotomy at the Hip Combined with Resection of Femoral Head. HENRY MILLER (Same Rm.)
 4. (a) Case Illustrating the Results of Tendon Transplantations and Nerve Suture, (b) Cases Illustrating Surgery of the Hand. LEO MAYER. (Same Rm.)
- 1:00-4:00. *Otolaryngology* Operative Clinic Nose and Throat Surgery. L. KLEINFELD (E-N T. Surg. O.R.—Capacity 5)

LENOX HILL HOSPITAL

- 1:00-4:00. *Plastic Surgery* Nonoperative Clinic: Demonstration of Cases. GORDON AUCHINCLOSS (Einhorn Auditorium—Capacity 450)

LYING-IN HOSPITAL

(See New York Hospital)

MANHATTAN EYE, EAR AND THROAT HOSPITAL

- 1:00-4:00. *Ophthalmology* Nonoperative Clinic. Demonstration Slit Lamp Demonstration. G. BONACCOLTO (5th Fl. Exam. Rm.—Capacity 15)
- Demonstration Corneal Grafting Technique on Rabbits. H. M. KATZ. (Same Rm.)
- 1:00-4:00. *Otolaryngology* Demonstration Biplane Fluoroscopy and Laminography. W. R. CARTER (X Ray Lab. 6th Fl.—Capacity 24)
- 3:00-5:00. *Ophthalmology* Demonstration Cases of Cataract Surgery Complicated by Glaucoma. M. A. LAST (Conference Rm. and FL—Capacity 24)

MEMORIAL HOSPITAL

- 10:00-12:00. *Tumor Surgery* Nonoperative Clinics Sloan Kettering Institute. Cancer Research in Relation to Clinical Problems
- Methods of Chemotherapy and Some Clinical Applications. (A survey of methods used in the screening program and their application to patients with leukemia.) J. BURCHENAL. (Auditorium—Capacity 250)
- Experiments on the Application of Chemotherapy Together with Conventional Methods. (Experimental

studies on the subject and examples of patients treated with mustards and x-rays) D. KARKOVSKY. (Same Rm.)

Cytochemical Studies of Mammary Cancer Including Observations During Hormone Therapy (Presentation of methods and findings which would not include any of the data that Dr. Adair might use in his talk.) R. MILLER. (Same Rm.)

Radioactive Iodine as a Tool in the Investigation and Treatment of Thyroid Cancer. F. FOOTE JR., Miss HULL. (Same Rm.)

Cases of Cancer of the Thyroid Treated with Radioactive Iodine. J. TRUMER, R. RAWSON. (Same Rm.)

METROPOLITAN HOSPITAL

100-400. *Neurosurgery* Nonoperative Clinic. Peripheral Vascular Clinic Including Sympathectomy. LOUIS R. KAUFMAN, S. THOMAS OLIVER, ALBERT LEBER, KENNETH C. PRACOCK, DAVID SCHERF. (Conference Rm.—Capacity 60).

MONTEFIORE HOSPITAL

100-400. *General Surgery* Nonoperative Clinic. SAMUEL STANDARD and STAFF. (Social Hall—Capacity 300).

400-500. *General Surgery* Nonoperative Clinic. Neoplastic Diseases. DANIEL LASKO. (Same Rm.)

MOUNT SINAI HOSPITAL

8:30-11:30. *Gynecology* Operative and Nonoperative Clinics

Parametrial Fixation Operation (Fothergill) Surgical Treatment of Urinary Strain Incontinence with Tanaka Plate. M. A. GOLDBERG. (Surg. Amphitheater—Capacity 60)

Conservative Surgery for Pelvic Endometriosis. JOSEPH GARDNER. (Same Rm.)

The Value of the Twenty-four Hour Pregnancy Test. Review of 500 cases. EMANUEL KLEMPERER. (Same Rm.)

The Clinical Value of Hystero-graphy. ARTHUR DAVID. (Same Rm.)

The Management of the Menopause. ROBERT I. WALTER. (Same Rm.)

100-500. *Neurosurgery* Nonoperative Clinics. Long Time Follow-up in Some Neurosurgical Cases. Case Presentations. ABRAHAM KAPLAN. (Surg. Amphitheater—Capacity 60)

Correlation of X-ray Findings and Clinical Picture. B. SCHERER. (Same Rm.)

Dumbbell Tumor of the Spine. IRA COHEN. (Same Rm.)

Craniospasty. Motion Picture Demonstration. S. GROSS. (Same Rm.)

NEW YORK EYE AND EAR INFIRMARY

100-300. *Otorhinolaryngology* Nonoperative Clinic. Frontal and Ethmoid Sinusitis—Preoperative and Follow-up. STUART L. CRAIG. (Clinic Rm.—Capacity 30)

100-300. *Otorhinolaryngology* Nonoperative Clinic. Adenoid Sinusitis—Preoperative and Follow-up. EARL F. LINDBACH. (Same Rm.)

400-600. *Otorhinolaryngology* Operative Clinic. Sinus Surgery. STUART L. CRAIG. (Same Rm.)

400-600. *Otorhinolaryngology* Operative Clinic. Surgery of the Antrum. EARL F. LINDBACH. (Same Rm.)

100-500. *Ophthalmology* Nonoperative Clinic. Preoperative Diagnostic Study. CONRAD BERNHEIM, H. ROMANIK and ASSOCIATES.

Preoperative and Postoperative Glaucoma Studies. W. KESKINGTON, H. ELWYN and ASSOCIATES.

Plastic Surgery Methods. W. HOOKER, J. COLE and ASSOCIATES. (Eye O.R. 10)

Special Lenses—Contact, Anisclonic and Telescopic Exhibit. (Clinic Fl.—Capacity 30)

The routine clinics of the New York Eye and Ear Infirmary will be held as usual during this period, all Fellows of the American College of Surgeons are cordially invited to attend.

NEW YORK HOSPITAL

100-500. *Genitourinary Surgery* Nonoperative Clinic. Demonstration. Surgical Anatomy. ERNEST LAMPE. (Bldg. A, Rm. 32—Capacity 50)

100-400. *General Surgery* Nonoperative Clinic. Demonstration. Surgical Anatomy. Detailed Anatomy of Radical Neck Dissection. ERNEST LAMPE. (Same Rm.)

100-500. *Otolaryngology*. Operative Clinic. Reconstructive Surgery of the Nose. ARTHUR PALMER. (10th Fl. O.R.—Capacity 30)

NEW YORK HOSPITAL

LYING-IN HOSPITAL

100-500. *Obstetrics and Gynecology* Nonoperative Clinics. Cryptomenorrhea—Congenital and Acquired. THOMAS L. BALL. (Lecture Room—Capacity 60)

Result of an Operation for Urinary Incontinence. ANDREW A. MARCHETTI, VICTOR MARSHALL. (Same Rm.)

Pregnancy Following Outlet Operation. WILLIAM FIDEL. (Same Rm.)

Studies on Patients with Hydramnios During the Past Fifteen Years. PAUL E. MULLER. (Same Rm.)

End-Results of the Treatment of Carcinoma of the Endometrium. ANDREW A. MARCHETTI, JOHN E. McALLISTER. (Same Rm.)

Radiological Survey of Breeches. H. L. WILSON. (Same Rm.)

NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL

8:00-100. *Orthopedic Surgery* Operative Clinic. ALAN DE FOREST SMITH and STAFF. (O.R. 1 and 2—Capacity 60)

10-400. *Orthopedic Surgery* General Orthopedic Clinic. HALFORD HALLOCK and STAFF. (7th Fl. Assembly Rm.—Capacity 30)

Congenital Club Foot Clinic. JOHN McCARTHY. (Same Rm.)

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL

8:30-100. *Tumor Surgery* Operative Clinic. H. W. MEXER. (O.R. 2—Capacity 10)

10-30. *Tumor Surgery* Nonoperative Clinic. Treatment and Late Results in Carcinoma of the Head, Neck and Breast. H. W. MEXER and STAFF. (Edmann Auditorium—Capacity 50)

100-500. *Vascular Surgery* Operative Clinic. GERALD PRATT. (O.R. 1—Capacity 10)

100-500. *General Surgery* Operative Clinic. J. W. HEDDER. (Amphitheater—Capacity 30)

100-500. *Orthopedic Surgery* Operative Clinic. G. ANTON. (O.R. 3—Capacity 10)

PRESBYTERIAN HOSPITAL

100-400. *General Surgery* Nonoperative Clinic. Carcinoma of the Tongue. A General Hospital. Analysis of 100 cases. JOHN M. HANCOCK. (McComb Amphitheater 18th Fl.—Capacity 140)

- Lymphatic Spread of Carcinoma of the Rectum and Colon. ROBERT S. GARDNER. (Same Rm.)
- Röntgen Diagnosis of Carcinoma of the Stomach. ROSS GOLDEN. (Same Rm.)
- Extent of Resection of Stomach for Carcinoma, Correlation with Experimental Mucus Transformation. Case Demonstration. EDWARD L. HOWES. (Same Rm.)
- Chemotherapy of Malignancy with Nitrogen Mustard. ALFRED GREENBERG. (Same Rm.)
- Surgical Anatomy. Demonstration of Autonomic Nerve Supply of the Gastrointestinal Tract. JOSEF FRIEDL. (Rm. 514, 10th Fl. Phys. & Surg. Bldg.—Capacity 50)
- Structures of the Female Perineum. PHILIP WITTELL. (Same Rm.)

PRESBYTERIAN HOSPITAL NEUROLOGICAL INSTITUTE

- 9:00-11:00. *Neurosurgery* Nonoperative Clinic. Neurosurgical Staff Conference. Clinical preview of surgical cases to be operated upon Tuesday and Friday mornings. Surgical Staff (Conference Rm. and Fl.—Capacity 60)
- Note: Regular operative clinics will be held every morning as usual and the visitors are welcome to attend.

PRESBYTERIAN HOSPITAL SLOANE HOSPITAL FOR WOMEN

- 10:00-12:00. *Obstetrics and Gynecology* Nonoperative and/or Operative Clinic. Demonstration of Delivery Room Technique and Teaching. Demonstration of Operative Obstetrics (if Cases Available). CHARLES STEER, ANTHONY D'ESORO, HOWARD C. MOLT. (17th Fl. Clinic or O.R. or Lecture Rm.—Capacity 50)

PRESBYTERIAN NEW YORK ORTHOPEDIC HOSPITALS Fracture Service

- 1:30-4:00. *Fractures and Traumatic Surgery* Nonoperative Clinic. Fracture Clinic. The Low Back Problem. SAWYER R. GASTON. (Rm. 417 16th Fl. Phys. and Surg. Bldg.—Capacity 100)
- Three, Four and Five Year Hip Fracture Follow-up Results. CHARLES S. NEILL. (Same Rm.)

ROOSEVELT HOSPITAL

- 1:00-4:00. *General Surgery* Nonoperative Clinic. Discussion. Post-Graduate Education of the Surgical Residents and Interns. CHARLES F. STEWART. (Conference Rm. 1—Capacity 50)
- 2:30-5:00. *Fractures and Traumatic Surgery* Nonoperative Clinic. Traumatic and Reconstructive Surgery of the Hand. CHARLES F. STEWART. (Conference Rm. 2—Capacity 50)
- The Early Treatment of Hand Injuries (Emergency Treatment). CONNOR W. CUTLER. (Same Rm.)
- The Repair of Finger Tip Injuries. HENRY A. KINGSBURY. (Same Rm.)
- The Temporary Repair of Severed Flexor Tendons of the Fingers. R. STELLING MUELLER. (Same Rm.)
- Reconstructive Surgery of the Hand. WILLIAM LATTIER.

ST LUKE'S HOSPITAL

- 8:30-11:00. *General Surgery* Operative Clinic. WILLIAM MACFARLANE and STAFF. (Lyle O.R.—Capacity 30)
- 11:00-1:00. *General Surgery* Nonoperative Clinics. Clinical Demonstrations. Neurofibromas of Stomach, six cases. JOHN WEST. (Staff Conference Rm.—Capacity 60)
- Management of Polyps of Colon and Rectum. PAUL MORTON. (Same Rm.)

- Adenocarcinoma of Colon and Rectum with Metastasis to Ovaries, illustrative cases. WILLIAM BERRY. (Same Rm.)
- Malignant Tumors of the Appendix. STAFFORD WEARN. Bleeding Duodenal Ulcers. ROBERT FRASER. (Same Rm.)
- Trends in Current Technique of Anesthesia. EDWARD BORDOW. (Same Rm.)
- 1:00-5:00. *Orthopedic Surgery* Operative Clinic. MATTHEW CLEVELAND and STAFF. DAVID BOSWORTH. (Lyle O.R.—Capacity 30)

ST VINCENT'S HOSPITAL

- 9:00-12:00. *General Surgery* Operative Clinic. General Surgery. RAYMOND P. SULLIVAN, JOHN A. LAWLER and GEORGE R. STUART. EDWARD DENCKEN. (Ward Bldg. O.R. A and B—Capacity 5 each, C, D and E—Capacity 10 each, F—Capacity 5)
- 9:00-12:00. *Thoracic Surgery* Nonoperative Clinic. Group Conference. Selection of Cases for Thoracoplasty, Lobectomy and Pneumonectomy. DANIEL MULVIHILL. (Nurse's Lecture Rm. and Fl.—Capacity 60)
- 9:00-12:00. *Radiology* Nonoperative Clinic. Röntgen Diagnosis of Thoracic Tumors. WILLIAM W. MAYER and ASSOCIATES. (Ward Bldg. Viewing Rm.—Capacity 25)
- 10:00-12:00. *Neurosurgery* Nonoperative Clinic. Follow up Study of a Series of Herniated Discs with Fusion of Spine. JAMES T. DANIELS, ANTHONY PIRAGI. (Nurse's Auditorium—Capacity 150)
- 1:00-5:00. *Pathology* Nonoperative Clinic. Clinical Pathological Demonstration of Hodgkin's Disease. Growth of Tissue Anterior Chamber of the Eye of Mice. ANTHONY ROTTINO. (Nurse's Auditorium—Capacity 60)
- Display and Demonstration of System Diseases by Kodachrome Slides. JOHN KRATING. (Same Rm.)
- Display of Fixed Specimens. WILLIAM F. MEEHAN. (Same Rm.)

U. S. MARINE HOSPITAL (STATEN ISLAND)

- 10:00-12:30. *General Surgery* Nonoperative Clinic. Inguinal Hernia (Follow-up Study). Postoperative Inguinal Hernia. HOMER L. SKINNER and STAFF. (Doctor's Staff Rm.—Capacity 75)
- 12:30-1:30. Luncheon at the Hospital.
- 1:00-3:00. *General Surgery* Operative Clinic. Inguinal Hernia under Spinal or Continuous Caudal Anesthesia. HOMER L. SKINNER and STAFF. (General O.R., 4th Fl.—Capacity 30)
- 3:00-3:30. *Auralis*. Nonoperative Clinic. Diagnostic and Prognostic Regional Block Clinic. C. L. HENERT and STAFF. (General O.R.—Capacity 5)

VETERANS ADMINISTRATION HOSPITAL

- 1:00-3:30. *General Surgery* Nonoperative Clinic. General Surgical Conference. FREDERICK W. BANCROFT, FOR DYCE B. ST. JOHN, ALLEN O. WHIPPLE, P. K. SAUER, CARLOS WEEKS, JOHN E. SULLIVAN, EDWIN SELF, DAVID K. POKOR, MARTIN J. HEALY and RESIDENT STAFF. (Bldg. A, 3rd Fl.—Capacity 100)
- 3:00-4:00. *General Surgery* Operative Clinic. Endoscopy. DAVID H. JONES, HENRY THALER. (Bldg. B, 5th Fl.—Capacity 5)
- 3:30-5:00. *Radiology* Nonoperative Clinic. Radiological Conference. CHARLES GOTTILIER, ARTHUR SIEGHELL, MAXWELL H. PORFEL, and STAFF. (Bldg. A, 3rd Fl.—Capacity 100)

CLINICS IN BROOKLYN—LONG ISLAND HOSPITALS

Monday

CUMBERLAND HOSPITAL

8:00-5:00. *General Surgery* Statistical Study Discussion of Postoperative Complications. DAVID J. GRAUBARD (Auditorium—Capacity 300).
Use of Sulfonamides in Acute Abdomen. MICHAEL VINCIGIARO. (Same Rm.)
Preoperative and Postoperative Treatment in Gastrointestinal Surgery. HARVEY COOPERMAN. (Same Rm.)
Advantages of Miller Abbott Tube in Small Bowel Obstruction. CESAREO CASTELLANETA. (Same Rm.)

Late Results in Surgery of Gastrointestinal Malignancy with Pathological Demonstration. HAROLD AXELSON

METHODIST HOSPITAL

9:00-1:00. *Plastic Surgery* Operative and Nonoperative Clinic: Plastic Repair of Cleft Palate. JOHN F. FORD. (Main O.R. 1-6—Capacity 1)
9:00-5:00. *Otolaryngology* Operative and Nonoperative Clinic: Otolaryngology. CHARLES A. ANDERSON, EDWIN A. STOWIE and STAFF. (Main O.R. 1-6—Capacity 50)

CLINICS IN NEW YORK HOSPITALS

Tuesday

BABIES HOSPITAL (See Presbyterian Hospital)

BELLEVUE HOSPITAL—FIRST (COLUMBIA UNIVERSITY) SURGICAL DIVISION

8:00-9:00. *General Surgery* Operative Clinic: FRANK B. BERRY and STAFF (O.R. A, B, C & D—Capacity 50)
8:00-1:00. *Thoracic Surgery* Operative Clinic: FRANK B. BERRY and STAFF (O.R. C & D—Capacity 1)
9:30-1:30. *Neurosurgery* Clinic (Stewart Amphitheatre 1 & 2 Bldg., Ground Fl.—Capacity 50)
Surgical methods in Treatment of Hypertension. CARLOS WIEGERS.
Chronic Thyroiditis. J. GORDON LEE.
Enterogenous Cysts. JAMES T. HAGO.
Treatment of Chronic Leg Ulcers by Fasciotomy. BENJAMIN J. REAM.
Preliminary Report Concerning Method for the Study of Peripheral Arterial Diseases. AARON HODGKINSON.

BELLEVUE HOSPITAL—SECOND (CORNELL UNIVERSITY) SURGICAL DIVISION

10:00-5:00. *Neurosurgery* Operative and Nonoperative Clinic. JOSEPH KING and WINFRED WINGENBACH. LAWRENCE POOL and HERBERT REINERT (O.R. K 5—Capacity 30)

BELLEVUE HOSPITAL—THIRD (NEW YORK UNIVERSITY) SURGICAL DIVISION

8:00-1:00. *Anesthesia* Operative and Nonoperative Clinic. Demonstrations. Anesthesia in Thoracic Surgery. E. A. ROYENSTONK and STAFF (5th Fl. C & D Bldg.—Capacity 5)
10:00-5:00. *General Rehabilitation* in General Hospital. Methods of Admission to Wards. GEORGE DRAVER, C. H. FURRY, J. (Wards F & G-3, F & G Bldg.—Capacity 5)

BETH ISRAEL HOSPITAL

9:00-1:00. *Plastic Surgery* Operative Clinic: ARTHUR E. BARKSY (O.R. A, 5th Fl.—Capacity 6).
1:00-5:00. *Genitourinary Surgery* Operative Clinic. STEPHEN WILHELM and STAFF. (Main O.R.—Capacity 30)
Nonoperative Clinic. STEPHEN WILHELM and STAFF (Auditorium—Capacity 300)

FLOWER AND FIFTH AVENUE HOSPITALS

9:00-1:00. *General Surgery* Operative Clinic: BREAST SURGERY. HERBERT C. CHASE. (Main O.R. 8th Fl.—Capacity 1)
Nonoperative Clinic: Biological Studies in Malignancy. I. S. KLEINER, M. M. BLACK. (Auditorium—Capacity 300)
10:00-1:00. *General Surgery* Nonoperative Clinic: Tumor Clinic. GEORGE T. PACK, JOHN Q. VISTA, GEORGE K. HODGES, and FRANK J. BOWELL. (Same Rm.)
12:00-4:00. *Thoracic Surgery* Nonoperative Clinic. Surgical Treatment of Angina Pectoris by the Establishment of Adhesive Pericarditis. Selection of the Patients; Operative Technique; Follow-up Results. SAMUEL A. THOMPSON, and M. J. RAINBORN. (Same Rm.)
4:00-5:00. *Gynecology* Nonoperative Clinic: Mammoplasty (Ayers Forceps, etc.) or—Ovarian Transplants. Two short moving pictures. BENJAMIN TOLL, HORACE AYER. (Same Rm.)

GOLDWATER MEMORIAL HOSPITAL— SECOND SURGICAL DIVISION

9:30-1:30. *Geriatric Surgery* Operative Clinic. CONRAD CUTLER and STAFF
Adductor Tenotomy and Obturator Nerve Section for Adductor Spasm. (Adm. Bldg., Main O.R. 3rd Fl.—Capacity 30).
Repair of Scrotal Hernia, Local Anesthesia. (Same Rm.)

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS

395

Amputation of Leg for Arteriosclerotic Gangrene: Re-
frigeration Anesthesia. (Same Rm.)
10:30-12:00. *Geriatric Surgery* Nonoperative Clinic: Case
Presentations

Anesthesia Methods in Bad Risk Patients. E. A. ROVEN
STEIN. (North Conference Rm., 3rd Fl. Between C
and D Pavilion—Capacity 50)

Clinical Studies in Chronic Peripheral Vascular Occlu-
sion. GRANT P. PENNYCOCKER. (Same Rm.)

Indications and Results of Hernia Repair in Old Pa-
tients. GEORGE STREIMER. (Same Rm.)

Problems in Chemical Balance in Geriatric Surgery
LOUIS CASE. (Same Rm.)

Dicoumarol and Other Anticoagulant Drugs. W. E.
ALSOOP. (Same Rm.)

Treatment of Chronic Bone Suppuration. F. B. ROTM.
(Same Rm.)

Cholecystitis Complicating Chronic Disease States.
W. T. MENDEL. (Same Rm.)

Urgent Surgery in the Aged. CONNOR W. CUTLER, JR.
(Same Rm.)

Clinical Pathological Demonstration. JULIUS ROSEN
THAL. (Same Rm.)

12:00-1:00. *Geriatric Surgery* Nonoperative Clinic: Case
Presentations

Arachnoiditis. JONATHAN OLJENICK. (B11 and B2—Capac-
ity 50)

Clinical Evaluation of Cystometric Readings. J. E.
BEAUMER. (Same Rm.)

Preliminary Report on the Experimental Studies of Ob-
struction at the Vesical Neck Complicating the Neu-
rogenic Bladder. ANDREW SPORER. (Same Rm.)

Vesical Neck Obstruction in the Female. LISA A. SALTZMAN
(Same Rm.)

Treatment of Incontinence in a Hospital for Chronic
Diseases. SAMUEL SOTTER. (Same Rm.)

Suprapubic Prostatectomy Modified Harris Technique
with Complete Closure. S. A. RITTER. (Same Rm.)

WARD ROUNDS

9:00-12:00. *Harlem Hospital*

Trauma Symposium and Ward Rounds: Injuries of
the Chest and Abdomen. R. L. YOUNG, J. C. WERT
AKER, R. S. WILKINSON, M. LOOAN, F. R. ALLEN,
Main Bldg. and Conference Rm. 5th Fl. Women's
Pavilion—Capacity 25

12:00-3:00. *Genitourinary Surgery* Nonoperative and Op-
erative Clinic: Genitourinary Conference, Ward
Downstairs and Operative Clinic. N. F. LASKY, E.
3C—Capacity 25

3:00-5:00. *Roentgenology* Nonoperative Clinics: Roent-
genology in Surgery

Regional Ileitis—Intestinal Obstruction. L. GINSBURG.
(Conference Rm. 5th Fl. Women's Pavilion—Capac-
ity 100)

Duodenal Loop Triad. WILLIAM SNOW. (Same Rm.)

HOSPITAL FOR JOINT DISEASES

9:00-12:00. *Orthopedic Surgery* Operative Clinic: Spine
Fusion for Scoliosis. Sauerization for Chronic Osteo-
myelitis. SAMUEL KLEINBERG, JOSEPH BUCHMAN
THOMAS HORWITZ. (Surg. Amphitheater—Capacity
50)

Nonoperative Clinic: Miller Operation for Flat Feet.
Use of Penicillin in the Operative Treatment of
Chronic Osteomyelitis. The Operative Treatment of
Cavus. Drilling of Incipient Epiphyseolysis at the

Hip. SAMUEL KLEINBERG, JOSEPH BUCHMAN THOMAS
HORWITZ. (Lecture Rm.—Capacity 60)

12:00-4:00. *Orthopedic Surgery* Nonoperative Clinic: Spec-
imen Demonstration: The Pathology of Bones and
Joints. HENRY JAFFE. (Same Rm.)

12:00-4:00. *Gynecology* Operative Clinic: Total Hysterec-
tomy for Uterine Tumors. Nonoperative Clinic: Fol-
low-up Results of Total Hysterectomy for Uterine
Tumors. HAROLD DAVIDSON. (Surg. Amphitheater—
Capacity 50)

12:00-4:00. *Plastic Surgery* Operative Clinic: Nasoplasty
Follow-up Clinic: Nasal, Lip and Face Plastic.
LEOPOLD GLUBERMAN. (Small O.R.—Capacity 5)

HOSPITAL FOR SPECIAL SURGERY

8:30-12:00. *General Surgery* Operative Clinic: Operations
by General Surgical Department. F. BEELMAN and
STAFF (Main O.R.—Capacity 35)

9:00-12:00. *Orthopedic Surgery* Nonoperative Clinic:
Children's Orthopedic Problems. PHILIP D. WILSON
and STAFF (Lecture Hall—Capac-
ity 100)

12:00-5:00. *Orthopedic Surgery* Nonoperative Clinic—
Knee Problems

Knee Capsuloplasty. LEWIS CLARK WAGNER. (Same
Rm.)

Quadricepsplasty to Improve Knee Function. T. CAMP-
BELL THOMPSON. (Same Rm.)

Conservative Treatment of Fractures of the Tibial
Plateau. ROBERT LEE PATTERSON. (Same Rm.)

Unusual Pathological Conditions Found in Knee Joints.
MILTON HELPERMAN. (Same Rm.)

Old Pathological Fractures of Femora Treated with
Knautecher Nail. JOHN R. COSS. (Same Rm.)

LENOX HILL HOSPITAL

9:00-11:00. *General Surgery* Operative Clinic. FRANKS
M. DOMINOVITZ and STAFF (O.R. 1 and 2—Capacity
each 15)

11:00-12:00. *General Surgery* Nonoperative Clinic: Ther-
apeutic Considerations in Acute Small Bowel Obstruc-
tion. ROBERT C. CROWLEY. (Elmhurst Auditorium—
Capacity 450)

12:00-5:00. *Urology* Nonoperative Clinics: Late Results
of Unusual Cases

Bilateral Stag Horn Renal Calculi. WILLIAM R. DEL
ZELL. (Elmhurst Auditorium—Capacity 450)

Stag Horn Calculus in Abnormally Rotated Pigeon Kid-
ney. HERBERT KATZMAN. (Same Rm.)

Horseshoe Kidney Resection of Hydronephrotic Half
MAXIMILIAN NEMER. (Same Rm.)

Operative Treatment of Large Dendritic Calculi of Soli-
tary Kidney. GEORGE SLAUGHTER. (Same Rm.)

LYING-IN HOSPITAL
(See New York Hospital)

MANHATTAN EYE, EAR AND THROAT
HOSPITAL

9:00-12:00. *Ophthalmology* Operative Clinic: Surgical
Treatment of Ptoxis of Lids, Operation and Results.
GURMERT FRYE. (Frey Clinic, 1st Fl., and Eye O.R.—
Capacity 5)

9:00-12:00. *Otolaryngology* Operative Clinic. Nasal
Plastic Operation. A. SCHATZNER. (O.R. 7th Fl.—
Capacity 5)

10:00-12:00. *Otolaryngology* Demonstration. Postopera-
tive Cases of Laryngectomy—Esophageal Voice Train-
ing. D. S. CUSHING. (Broncho. Clinic, 3rd Fl.—
Capacity 15)

- 3:00-4:00. *Ophthalmology* Operative Clinic Surgical Treatment of Strabismus, Operations and End Results. F. C. KELL. (Eye O.R., 6th Fl.—Capacity 5)
- 4:00-5:00. *Ophthalmology* Orthoptic Clinic. F. C. KELL, JR., E. KNAUBER. (Orth. Clinic, 1st Fl. Rear—Capacity 1)
- 5:00-7:00. *Otolaryngology* Operative Clinic: Laryngotomy D. S. CONNING (7th Fl. O.R.—Capacity 5)
- 7:00-8:00. *Otolaryngology* Operative Clinic: Nasal Plastic Operation. WILLIAM B. ALLAN (7th Fl. O.R.—Capacity 5)
- 8:00-9:00. *Otolaryngology* Clinicopathological Demonstration: Malignancy of the Larynx. A. A. EGGERTS, D. S. CONNING. (Conference Rm. 2nd Fl.—Capacity 50)

MEMORIAL HOSPITAL

- 8:00-9:00. *Tumor Surgery* Operative Clinics. FRANK E. ADAMS, O. E. BINKLEY, B. L. COLEY, A. L. DEAN, V. F. MARSHALL, HAYES MARTIN, OYGEOR T. PACK, O. H. TWOMBLY, W. L. W. TUCKER (O.R. A—Capacity 5; O.R. B—Capacity 5; O.R. C—Capacity 5; O.R. D—Capacity 5; O.R. E—Capacity 5)
- 9:00-10:00. *Tumor Surgery* Nonoperative Clinics: Discussion.
- The Memorial Hospital Nomenclature for Cancer and Its Usefulness in Cancer Hospitals, Cancer Clinics, and Cancer Commissions. ELIZABETH MACDONALD. (Auditorium—Capacity 50)
- The Necessity for Uniform and Accurate Methods of Reporting Cancer Statistics: Cure Rates in Cancer Based Upon Total Experience. HAYES MARTIN (Same Rm.)
- The Organization of the Statistics Department of Memorial Hospital and a Report of Five-year End-Results in Various Anatomic Forms of Cancer as Calculated by the Statistics Department to Date. MARY MACDONALD. (Same Rm.)
- 10:00-11:00. *Tumor Surgery*, Nonoperative Clinic: Follow-up Patients With Total Laryngectomy for Cancer of the Larynx. (Same Rm.)
- 11:00-12:00. *Tumor Surgery* Nonoperative Clinic: Follow-up Patients Illustrating Combined Neck Dissection and Excision of Primary Lesions of the Mouth. (Same Rm.)

METROPOLITAN HOSPITAL

- 9:00-10:00. *General Surgery* Operative and Nonoperative Clinic: Thyroid Surgery and Resident Training. JAMES M. WENTFIELD and STAFF (Main O.R. and Conference Rm.—Capacity 60)
- 10:00-11:00. *Genitourinary Surgery* Operative Clinic: Plastic Correction of Hydronephrosis, Ureterodysgenesis. SPRAGUE CARLETON and STAFF (Main O.R.—Capacity 30; O.R.—Capacity 5; O.R. 3—Capacity 5)
- Nonoperative Clinic: Demonstration Selected Cases Exhibit of Staff Training; Clinical Exhibit. SPRAGUE CARLETON and STAFF (Same Rm.)

MONTEFIORE HOSPITAL

- 3:00-4:00. *General Surgery* Nonoperative Clinic: Mildly Amputations in Diabetes. SAMUEL SILBERT (Social Hall—Capacity 300)

MOUNT SINAI HOSPITAL

- 8:30-10:00. *Genitourinary Surgery* Operative Clinic: Resection of the Rectum. Colectomy for Ulcerative Colitis. JOHN GARLOCK. (Surg. Amph.—Capacity 100)

- Nonoperative Clinic and Case Presentations. JOHN GARLOCK, LEON GINSBURG, SAMUEL KLEIN, ARTHUR GLASS, GABRIEL STELEY. (Same Rm.)
- 12:00-1:00. *Orthopedic Surgery* Operative and Nonoperative Clinic. ROBERT LIPPMAH, ALBERT SCHULZ, EDGAR BICK. (Same Rm.)

NEUROLOGICAL INSTITUTE

(See Presbyterian Hospital)

NEW YORK EYE AND EAR INFIRMARY

- 10:00-11:00. *Otolaryngology* Demonstration: Soundproof Room and Testing. J. SWIFT HANLEY. (Soundproof Rm. and Adjacent Rm.—Capacity 30)
- 11:00-12:00. *Otolaryngology* Demonstration: Frontal Sinus Surgery by Motion Pictures. J. SWIFT HANLEY. (Same Rm.)
- 4:00-6:00. *Otolaryngology* Nonoperative Clinic: Sinus Surgery. J. SWIFT HANLEY. (Weeks Hall—Capacity 50)
- 4:00-6:00. *Otolaryngology* Nonoperative Clinic: Radical Mastoidectomy. VIRGINIUS B. HIRST.
- 8:00-9:00. *Ophthalmology* Nonoperative Clinic. Postoperative Results with Study of Operative Complications. BOYES and ASSOCIATES.
- The Distribution of Newly Examined Patients and Outlines for Further Studies. R. PAYNE and R. MCCASLAN and ASSOCIATES. (Clinic Rm.—Capacity 30)
- Operative Clinic: Surgical Techniques with Reference to Lids and Glaucoma. R. MINK and W. JONKHOFF and ASSOCIATES. (Eye O.R.—Capacity 10)
- Orthoptic Department—Muscle Anomalies. (Orthoptic Clinic—Capacity 30)
- The routine clinics of the New York Eye and Ear Infirmary will be held as usual during this period, all Fellows of the American College of Surgeons are cordially invited to attend.

NEW YORK HOSPITAL

- 9:00-10:00. *Thoracic Surgery* Operative and Nonoperative Clinics. FRANK GLENN and STAFF
- Surgery of Mediastinal Tumors. WILLIAM DEW ANDERSON. (10th Fl. Amphitheater and Rm. F-630—Capacity 60). Follow-up Studies of Mediastinal Tumors. JOHN ECKER. (Same Rm.)
- Chronic Constrictive Pericarditis. Surgical Aspects. WILLIAM DEW ANDERSON. (Same Rm.)
- Diagnosis of Carcinoma from Degenerated Cells. GEORGE PAPADAKALOS. (Same Rm.)
- Clinical Value of Sputum Diagnosis. HENRY CHOCHELLI. WILLIAM A. BAUMER. (Same Rm.)
- 9:00-10:00. *Genitourinary Surgery* Operative and Nonoperative Clinics. (From the Department of Surgery, New York Hospital—James Buchanan Brady Foundation).
- Perineal Prostatectomy. THOMAS J. KIRWIN. (Surg. Amphitheater—Capacity 100)
- Demonstration of Spinal Anesthesia. ROSE ARNOLD. (Same Rm.)
- Uretropericic Obstruction. ROY B. HENKLE. (Same Rm.)
- Absorbable Gauze in Urologic Surgery. GEORGE FRIEDLER. (Same Rm.)
- Case Report. THOMAS P. TWIDDE. (Same Rm.)
- True Adrenal Tumor of Kidney. ROBERT W. HUNT. (Same Rm.)
- Ureteral Obstruction in Relation to Psychosis. C. K. CHURCH. (Same Rm.)
- Treatment of Bladder Tuberculosis with a New Instrument and Method. STANLEY WANG. (Same Rm.)

- Glands in Female Urethra of the Infant. FRANCIS BENKE VENTIL. (Same Rm.)
- Foreign Body in Ureter. ALBERT VIERCKS-PLAUER. (Same Rm.)
- Transplantation of Ureters. ALFONSO AVALOS. (Same Rm.)
- Case Report. PAUL BOYD ALBERTO GENTILE, WAYNE HANSON CECIL HAWES. (Same Rm.)
- Demonstration of Drawings of Interesting Urological Cases and Operations. WILLIAM P. DIDURCH. (Room F-956—Capacity 100)
- Motion Pictures of Urological Operations. WILLIAM P. DIDURCH. (Room F-901—Capacity 100)
- 1:00-5:00. *General Surgery* Nonoperative Clinic: General Surgery. FRANK GLENN and STAFF
- The Resident System in Surgical Training at the New York Hospital. FRANK GLENN. (Room B-001—Capacity 350)
- Follow-up Results—Carcinoma of Breast, Stomach, Colon, Rectum. WILLIAM A. COOPER. (Same Rm.)
- Organization of Follow-up Clinic. BROOKS S. RAY. (Same Rm.)
- Demonstration. Follow up Clinic Staff. (Same Rm.)
- 1:00-5:00. *Gynecology* Operative and Non-operative Clinics
- The Treatment of Bladder Tumors (From the Department of Surgery, Cornell University Medical College, and Memorial and Bellevue Hospitals). VICTOR F. MARSHALL and STAFF
- Classification of Bladder Tumors. JOHN W. DRAPER. (Surg. Amphitheatre—Capacity 100)
- Results of Radiation Therapy of Bladder Tumor. VICTOR F. MARSHALL. (Same Rm.)
- Transurethral Treatment of Bladder Tumors. ALLISTER M. MCLELLAN. (Same Rm.)
- Bladder Resection for Bladder Tumor. J. EDWIN DREW. (Same Rm.)
- Uretero-Cutaneous Transplantation. GUSTAVUS A. HUMPHREYS. (Same Rm.)
- Ureterointestinal Anastomosis. MORRIS SCHNEITMAN. (Same Rm.)
- Total Cystectomy. WILLET F. WHITMORE. (Same Rm.)
- Management of Advanced Carcinoma of the Bladder. ROBERT S. HOTCHKISS. (Same Rm.)
- Summary and Conclusions. VICTOR F. MARSHALL. (Same Rm.)
- 1:00-5:00. *Otolaryngology* Operative Clinic: Surgery of the Mastoid. GERVAIS MCGAULFEE. (10th Fl. O.R. 1 Rm.—Capacity 30)
- 1:00-4:00. *General Surgery* Nonoperative Clinic: Surgical Anatomy Demonstration. Anatomy of the Hand Involved in Infection and Trauma. ERNEST W. LAMPE. (Room A 133—Capacity 15)

NEW YORK HOSPITAL LYING-IN HOSPITAL

- 9:00-12:00. *Obstetrics and Gynecology* Operative and Non-operative Clinics
- Operation for Correction of Prolapse. BYRON GOFF. (Gyn. O.R., 2 Rms.—Capacity 50)
- Extrapelvic Cesarean Section. CURTIS MICKELSON. (Same Rm.)
- Extrapelvic Cesarean Section (moving picture). HERVEY WILLIAMSON. (Lecture Rm.—Capacity 100)
- 1:00-5:00. *Obstetrics and Gynecology* Nonoperative Clinic: Artificial Impregnation—Late Results. WILLIAM H. CAREY. (Same Rm.)
- Clinic for Treatment and Study of Amenorrhea. RALPH W. GAUTIER. (Same Rm.)

- Cardiac Disease in Pregnancy. CURTIS L. MICKELSON. (Same Rm.)
- Transfusion Reactions Due to Rh Incompatibility. ELMER KRAMER. (Same Rm.)
- Obstetrical Experience in Rh-negative Women. JOHN T. COLE. (Same Rm.)
- End-Results of Patients with Infertility. CHARLES M. McLANE. (Same Rm.)

NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL

- 9:00-12:00. *Orthopedic Surgery* Rounds. End-Result Conference. ALAN DE FOREST SMITH. (7th Fl. Assembly Rm.—Capacity 30)
- Low Back Pain and Herniation of the Nucleus Pulposus. ALAN DE FOREST SMITH. (Same Rm.)
- Suppurative Arthritis. HALFORD HALLOCK. (Same Rm.)
- 1:30-4:00. *Orthopedic Surgery* General Orthopedic Clinic. LEONIDAS A. LANTOUMIS and STAFF. (Same Rm.)
- Scoliosis Clinic. WILLIAM VON LOCKUM. (Same Rm.)

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL

- 8:30-11:30. *Urology* Operative Clinic. CLARENCE BAWDLER. (O.R. 5—Capacity 10)
- 8:30-12:00. *Plastic Surgery* Operative Clinic. GUSTAVE AUFRICHT. (O.R. 3—Capacity 10)
- 10:30-12:30. *Neurosurgery* Nonoperative Clinic: Case Presentations of Thoracolumbar Sympathectomy for Essential Hypertension. JEROME W. LORD JR., S. ARTHUR LOCALIO. (Erdmann Auditorium—Capacity 125)
- 11:30-1:00. *Oral Surgery* Operative Clinic. F. S. DUNN. (O.R. 5—Capacity 10)
- 1:00-5:00. *Thoracic Surgery* Operative Clinic. L. R. DAVIDSON. (O.R. 4—Capacity 10)
- 1:00-5:00. *General Surgery* Operative Clinic. R. F. CARTER. (O.R. 5—Cap. 10)
- 1:00-5:00. *Gynecology* Operative Clinic. W. T. DANN REUTHER. (Surg. Amphitheatre—Capacity 50)

PRESBYTERIAN HOSPITAL

- 8:00-12:00. *General Surgery* Operative Clinics: Thoracic Surgery. GEORGE H. HUMPHREYS, HERBERT C. MAIER, RICHMOND L. MOORE. (Balcony Fl. 19, Main O.R. C-F—Capacity each 16)
- Thyroid Surgery. WILLIAM B. PARSONS, LAWRENCE W. SLOAN, ROBERT H. E. ELLIOTT. (Same Rm.)
- 8:00-12:00. *Plastic Surgery* Operative Clinics
- Plastic Operations. JEROME P. WEBSTER. (Balcony Fl. 19, Main O.R. G and H—Capacity each 16)
- Release of Burn Contracture of the Neck. THOMAS W. STEVENSON. (Same Rm.)
- 1:00-4:00. *General Surgery* Nonoperative Clinic: Surgical Treatment of Esophageal Neoplasms. GEORGE H. HUMPHREYS. (Amphitheatre A, Main Fl. Phys. and Surg. Bldg.—Capacity 235)
- The Surgical Treatment of Bronchiectasis. RICHMOND L. MOORE. (Same Rm.)
- Mediastinal Tumors. HERBERT C. MAIER. (Same Rm.)
- Thoracoabdominal Injuries. ROBERT H. WYLIE. (Same Rm.)
- Surgery of Tumors of the Ampulla of Vater and Head of Pancreas. WILLIAM B. PARSONS. (Same Rm.)
- Results of Partial Gastrectomy for Peptic Ulcer. HAROLD D. HARVEY. (Same Rm.)
- 1:00-4:00. *General Surgery* Nonoperative Clinics: Experiences with Anticoagulants in the Treatment of Thromboembolism. DAVID V. HABIB. (McCosh Amphitheatre 18th Fl.—Capacity 142)

Follow-up Results in Thyroid Operations. LAWRENCE W. STOKES (Same Rm.)

Physiological Studies in Injuries Due to Cold. OCTA C. LEROY (Same Rm.)

200-400. *Plastic Surgery Nonoperative Clinic:* Cases of Mammoplasty with Nipple and Areola Transplantation. Plastic Repair after Excision of Carcinoma. Plastic Repair after Extensive Burns. Plastic Repair of Miscellaneous Conditions. JEROME P. WENSTER. (Rm. 4 7 16th Fl. Phys. and Surg. Bldg.—Capacity 60)

Synovitis of the Wrist. Surgical Repair of X-Ray Burns. THOMAS W. STEVENSON (Same Rm.)

PRESBYTERIAN HOSPITAL BABIES HOSPITAL

9:00-11:00. *General Surgery Operative Clinic.* EDWARD J. DONOVAN and STAFF (O.R. and 2, 9th Fl.—Capacity each 5)

1 100-1 200. *General Surgery Nonoperative Clinic:* Presentation of Current Cases. (Ward Rounds—Capacity 10)

200-400. *General Surgery Nonoperative Clinic:* Congenital Hypertrophic Pyloric Stenosis. Report of 600 Consecutive Cases with Follow-up. EDWARD J. DONOVAN (Amphitheater 4th Fl.—Capacity 75)
Splenectomy in Children with Observations on Portocaval Anastomosis. LOUIS M. ROUSSELLOTT (Same Rm.)
Duplications of the Alimentary Tract. Report of Seven Cases with Follow-up. THOMAS V. SANTUCCI (Same Rm.)
Intussusception. BREYER M. HODG. (Same Rm.)

PRESBYTERIAN HOSPITAL NEUROLOGICAL INSTITUTE

9:00-11:00. *Neurosurgery Operative Clinic:* Cases Previously Shown Clinically. 1 the Monday Morning Staff Conference. Surgical Staff (10th Fl. N.L.—O.R.—Capacity 2, O.R. 2—Capacity 6) Clinical Preview of Surgical Cases to be Operated Upon Wednesday Thursday and Friday Mornings. Guests Welcomed.

1 30-1:00. Luncheon—Bard Hall.

200-400. *Neurosurgery Nonoperative Clinic:* Summary Presentations of Current Research Projects. (2nd Fl. Conference Rm.—Capacity 60)

Experimental Production of Acute Disseminated Encephalomyelitis in Monkeys. ELVIN KARAT, ARTHUR WOLFF

Experimental Studies of the Function of the Pyramidal System in Monkeys. FRED MATTIOLI

Localization of Level Lesions of the Spinal Cord by Electromyography. PAUL F. A. HOKKER

Results of Treatment of Nonobstructive Hydrocephalus. Five-year Follow-up. JAMES E. SCARRY

Premature Synostosis of the Sutures of the Cranial Vault—Treatment and Results. LESTER A. MOYER

Incidence of Convulsions Following Depressed Fractures of the Skull. A Follow-up Study. FRED CRAMER

Surgical Procedures Directed to the Relief of Involuntary Mass Reflexes in Paraplegic Patients. J. LAWRENCE POOL

Congenital Dermal Sinuses Subdural Abscess; Abscess of Spinal Cord. LESTER A. MOYER

Anomalous Pachionian Granulations as a Factor in Certain Types of Focal Epilepsy. Case Reports. JAMES E. SCARRY

Therapeutic Applications of Curare Derivatives in Neurology—Motion Pictures. EDWARD B. SCHLESINGER

4 30-5:00. Refreshments.

PRESBYTERIAN HOSPITAL SLOANE HOSPITAL FOR WOMEN

1 100- 200. *Obstetrics and Gynecology.* Nonoperative and/or Operative Clinic: Demonstration of Delivery Room Techniques and Teaching. Demonstration of Operative Obstetrics if Cases Available. CHARLES STEIN, ANTHONY D'EAONO, HOWARD C. MOLOY (7th Fl. Clinic or O.R. or Lecture Rm.—Capacity 20)

200-300. *Obstetrics and Gynecology.* Nonoperative Clinic: Late Results in Cesarean Section. ANTHONY D'EAONO. (7th Fl. Lecture Rm.—Capacity 40)

300-400. *Obstetrics and Gynecology.* Nonoperative Clinic: Use of Stereocentgenograms in the Diagnosis of Pelvic Types. HOWARD C. MOLOY (Same Rm.)

400-500. *Obstetrics and Gynecology.* Nonoperative Clinic: Relation of Size of Fetal Head to Pelvic Inlet as Identified by Stereocentgenograms. CHARLES STEIN. (Same Rm.)

PRESBYTERIAN NEW YORK ORTHOPEDIC HOSPITALS

Fracture Service

9:00-12:00. *Fractures and Traumatic Surgery.* Operative Clinic. FRACTURE SERVICE STAFF (Fresh Hop. Balcony, 9th Fl. Main O.R.—Capacity 8)

1200-400. *Orthopedic Surgery.* Nonoperative Clinic: Fracture Follow-up Clinic. FRACTURE SERVICE STAFF. (Rm. 237, 3rd Fl. Vanderbilt Clinic—Capacity 20)

400-500. *Orthopedic Surgery.* Nonoperative Clinic: X-Ray Review. FRACTURE SERVICE STAFF (X-ray Rm. 75, Main Fl. Fresh Hop.—Capacity 36)

ROOSEVELT HOSPITAL

200-400. *General Surgery.* Nonoperative Clinic: Surgical Treatment of Lesions of the Colon.

The Management of Polyps and Papillomas of the Rectum. FREDERICK H. ANDERSON. (Conference Rm. 1—Capacity 20)

Pathology of Ulcerative Colitis. Gross and Microscopic Specimens (Illustrative Lantern Slides). WALTER W. BRANTNER. (Same Rm.)

ST LUKE'S HOSPITAL

8:30- 200. *General Surgery.* Operative Clinic. WILLIAM MACFEE and STAFF (Lyle O.R.—Capacity 20)

200-400. *General Surgery.* Nonoperative Clinic: Clinical Demonstrations. Unusual Aspects of Otherwise "Incurable" Tumors. FRANKIE CARTER WOOD. (Staff Conference Rm.—Capacity 60)

Carcinoma of Breast, Ten-year Follow-up. BENJAMIN SCHWARTZ. (Same Rm.)

1 100-200. *Otolaryngology.* Operative Clinic: Operative Clinic and Clinical Demonstrations. WILSON FORTKES and STAFF (Lyle O.R.—Capacity 6)

ST VINCENT'S HOSPITAL

9:00- 200. *General Surgery.* Operative Clinic: General Surgery. CONSTANTINE J. MACUTER, CLARENCE F. HOWLEY, LOUIS SURGAK. (O.R. A—Capacity 12)

9:00-1200. *General Surgery.* Operative and Nonoperative Clinic: Surgery of the Large Bowel. FRANK X. THOMAS, G. E. BRIDLEY, M. R. DEODINE. (O.R. C—Capacity 20)

9:00- 200. *Pathology.* Nonoperative Clinic: Report on Study of the Question of Retrolymphatic Spread in Carcinoma of the Rectum. J. F. COONELL. (O.R. D—Capacity 20)

9:00- 200. *Genitourinary Surgery.* Nonoperative Clinic: Case Presentation. Diagnosis and Surgical Diseases of the Kidney. THOMAS F. HAWLEY, J. EDWIN DUFFY (Nurse's Lecture Rm.—Capacity 60)

- 2:00-3:00. *Plastic Surgery* Nonoperative Clinic: Round Table Discussion Cleft Lip and Palate. Syndactylism. Skin Grafting of Burns. Postoperative Results and Presentation of Patients. WALTER A. COAKLEY ROBERT H. CLIFFORD (Same Rm.)
- 2:00-4:00. *Otolaryngology* Operative Clinic and Demonstration Oral and Laryngeal Malignancies and Non-Malignancies. JOHN M. LOKE and ASSOCIATES. (O.R. D.—Capacity 10)
- 2:00-4:00. *Pathology* Nonoperative Clinic: Display and Demonstration System Diseases by Kodachrome Slides. ANTHONY ROTTINO and ASSOCIATES. (Nurse's Home, Lab.—Capacity 30)
- 2:00-4:00. *Neurosurgery* Nonoperative Clinic: Surgical Treatment of Tuberculoma of the Brain Supplemented with Streptomycin. T. Q. GARVEY JR. (Nurse's Lecture Rm.—Capacity 60)
- Morphology of the Oligodendroglia Demonstrated by a New Method. ANTONIO GRIMO. (Same Rm.)

U. S. MARINE HOSPITAL (STATEN ISLAND)

- 10:00-12:30. *Orthopedic Surgery* Nonoperative Clinic. A. A. MICHELLE and STAFF
- Fracture of Olecranon (Doctor's Staff Rm.—Capacity 75)
- Fracture of Patella. Discussion and Presentation of Cases. (Same Rm.)
- Treatment of Injuries First Metacarpal-carpal Joint. (Same Rm.)
- Trepaine Vertebral Body (Same Rm.)
- 9:00-12:30. *Thoracic Surgery* Operative Clinics First Stage Thoracoplasty Under Balanced Anesthesia. Pneumonectomy H. L. SKINNER, R. K. IVERSON L. R. DAVIDSON (General O.R.—Capacity 20)
- 12:30-1:30. Luncheon at the Hospital.
- 1:00-3:00. *General Surgery* Nonoperative Clinic: Surgical Ward Rounds. W. F. NICKEL and RESIDENT STAFF (Surg. Wards 3rd & 4th Fl.—Capacity 75)
- 1:00-3:00. *Orthopedic Surgery* Operative Clinic: Iliac Graft Non-union of Tibia. A. A. MICHELLE and STAFF (General O.R.—Capacity 10)
- 2:00-4:00. *Thoracic Surgery* Nonoperative Clinics Echinococcal Cyst. Discussion and Case Presentation. Chest Conference. R. K. IVERSON (Doctor's Staff Rm.—Capacity 75)
- 2:30-4:00. *Anesthesiology* Nonoperative Clinic Intravenous Proximal Therapy for Palatal Orthopedic Condition. H. L. HERBERT and STAFF (General O.R.—Capacity 5)

VETERANS ADMINISTRATION HOSPITAL

- 9:00-12:00. *General Surgery* Operative Clinics. DAVID K. PINKES, EDWIN SELF JOHN E. SULLIVAN (Bldg. D 2 Rm., 12th Fl.—Capacity 20)
- 9:00-12:00. *Genitourinary Surgery* Operative Clinic. LOUIS SWACK, PERRIN SWIDEN, WILLET F. WHITMORE. (Bldg. D 1 Rm., 12th Fl.—Capacity 10)

- 9:00-12:00. *Plastic Surgery* Operative Clinic. HERBERT CONWAY ROBERT H. CLIFFORD (Bldg. B 1 Rm., 5th Fl.—Capacity 10)
- 9:00-12:00. *Radiology* Radiotherapy of Head and Neck. RALPH E. HENDERSON BERNARD ROSWIT (Bldg. C, Ground Fl.—Capacity 50)
- 9:00-12:00. *Otolaryngology* Operative Clinic. SYL VENTER DALY (Bldg. B 5th Fl.—Capacity 5)
- 9:30-11:30. *General Surgery* Nonoperative Clinic Medical Rehabilitation Clinic. HARRY KESSLER, EARL HARFUDER, IRWIN D. STEIN BERNARD STOLL, JACOB BYER. (Bldgs. B-C F Ground Fl.—Capacity 20)
- 11:00-12:30. *General Surgery* Nonoperative Clinic: Results of Operation for Carcinoma of the Rectum. DAVID K. PINKES. (Bldg. A, Ground Fl.—Capacity 300)
- 1:30-3:30. *General Surgery* Nonoperative Clinic: Conference Tumor Board. FRED STEWART P. K. SAUER, ERNEST S. OLSON BERNARD ROSWIT BERNARD STRAUSS, R. L. LA CANOVA, and RESIDENT STAFF (Bldg. A, 3rd Fl.—Capacity 300)
- 3:30-5:00. *Pathology* Nonoperative Clinic Conference Biopsies. FRED STEWART (Same Rm.)
- Scintillation to Rh-sub group. Case Report. ERNEST S. OLSON (Same Rm.)
- Results of Streptomycin in Tuberculosis of the Kidney MORRIS RAKETEM (Same Rm.)
- Hemoglobinuric Nephrosis. ARTHUR C. ALLEN (Same Rm.)
- Carcinoma of Islands of Langerhans Treated with Alloxan. BENJAMIN S. GORDON (Same Rm.)

EXHIBITS (Bldg. A, 3rd Fl.)

- | | |
|-----------------------------------|----------------------------|
| Anesthesia Section | Results of Vagus Resection |
| Brochogenic Carcinoma | Pathology Section |
| Review of 600 Cases | Medical Illustrations |
| Intracranial Neoplasms | Laboratory |
| Residency Training Program | Plastic Surgery |
| Organization of Surgical Division | Prosthetic Appliances |

WOMAN'S HOSPITAL

- 8:30-12:30. *Obstetrics and Gynecology* Nonoperative Clinics ALBERT ALDRIDGE and STAFF
- Treatment of Neoplasms of the Female Genital Tract. Management of Birth Injuries and Uterine Displacements. (4th Fl. Conference Rm.—Capacity 75)
- Diagnosis and Treatment of Obstetric Complications. End Results of Treatment of These Conditions Will Be Discussed. (Same Rm.)
- During the course of the morning the routine for training of Residents in Gynecology and Obstetrics will be outlined. (Same Rm.)
- The pathologist will give demonstrations of obstetric and gynecologic pathological specimens. (Same Rm.)

CLINICS IN BROOKLYN—LONG ISLAND HOSPITALS

Tuesday

CUMBERLAND HOSPITAL

- 9:00-12:00. *Gynecology* Operative Clinic Gynecological Operations. SAMUEL LUBIN and STAFF (O.R. 1 & 2—Capacity 20)
- Preoperative and Postoperative Care of Gynecological Patients. CHARLES N. LOUGHRAN and STAFF (Same Rm.)

- 10:30-11:00. *Gynecology* Nonoperative Clinic Granuloma Inguinale (Venereum) of Uterus—Follow up. SILEX H. POLAYZ. (Auditorium—Capacity 300)
- 2:00-4:30. *General Surgery* Nonoperative Clinic Immunization with A & B Factors in Erythroblastosis Fetalis SILEX H. POLAYZ. (Same Rm.)

Importance of Blood and Blood Derivatives in Obstetrics. **LESLIE H. THORALL**. (Same Rm.)
 Conservative Management of Abortions. **RICHARD WALTMAN**. (Same Rm.)
 Bacillus Welchii Postpartum Infection, Late Results. **CHARLES LOUGHRAN**. (Same Rm.)

JEWISH HOSPITAL

8:00-10:00. *General Surgery* Operative Clinics. **LOUIS BERGER** and STAFF. (Main O.R. Amphitheatre 1 & 2. Capacity each 35)
 10:00-12:00. *General Surgery* Nonoperative Clinic: Fascial Transplants in Repair of Large Inguinal Hernia. **LOUIS J. MORSE**, **JACOB S. BARR**. (Auditorium—Capacity 200)
 Bacillus welchii Infections of the Biliary Tract. (Same Rm.)
 The Perforated Gall Bladder. **BERNARD PETER**. (Same Rm.)
 Pitfalls in the Diagnosing and Surgical Therapy of Obstructive Jaundice. **HYMAN L. HERSHMAN**, PA & ASSOCIATES. (Same Rm.)
 Experiences with Resection of the Vagus Nerve in the Treatment of Peptic Ulcer. **THEODORE ARNETT**. (Same Rm.)
 Bowel Perforation with Miller Abbott Tube. **SAMUEL ACORN**. (Same Rm.)
 Carcinoma of the Small Bowel. **DAVID FARRER**. (Same Rm.)
 Delayed Verrus Immediate Intestinal Anastomosis. **LOUIS VERRIER**. (Same Rm.)
 Surgical Indications in Chronic Ulcerative Colitis. **RALPH WOLFE**. (Same Rm.)

KINGS COUNTY HOSPITAL

8:30-10:00. *Obstetrics and Gynecology* Operative Clinics (Long Island College Service). **CHARLES A. GORDON**, **M. GLASS**, **W. S. MCGREGOR** and **F. P. LIGHT**. (B. Bldg. O.R. 6—Capacity 5)
 9:30-10:00. *General Surgery* Operative Clinic: Operation for Carcinoma of the Colon. **BENJAMIN CISEL** and STAFF. (Same Rm.)
 9:30-10:00. *General Surgery* Operative Clinics: Subdiaphragmatic Vagus Neurectomy. **GEORGE G. DIXON** and STAFF. (Same Rm.)
 10:00-12:00. *General Surgery* Nonoperative Clinic.
 End-Result of Resection of the Head of the Pancreas in Carcinoma. **BENJAMIN CISEL** and STAFF. (O.P.D. Bldg. Lecture Rm.—Capacity 100)
 End-Result of Embolization of the External Iliac Artery. (Same Rm.)
 Follow-up on Repair of Arteriovenous Fistula. **BENJAMIN CISEL** and STAFF. (O.P.D. Bldg. Lecture Rm.—Capacity 100)
 Follow-up on Unusual Results With Internal Fixation for Fracture of Femoral Neck. **BENJAMIN CISEL** and STAFF. (Same Rm.)
 10:00-12:00. *General Surgery* Nonoperative Clinic.
 Report on a Series of Vagus Neurectomies.

Gastroscopy and Gastric Surgery. (RICHARD SCHWARTZ by request). (Main Bldg. Rm. B-3—Capacity 50)
 Replacement Therapy by Massive Transfusions in Gastrointestinal Hemorrhage. (VICTOR GOSSEN by request). (Same Rm.)

12:00-1:00. *Obstetrics and Gynecology* Nonoperative Clinic: Gynecology. (Main Bldg. Lecture Rm. 1st Fl.—Capacity 40)
 1:00-2:00. *Orthopedic Surgery* Nonoperative Clinic: **JOSEPH B. L'ETECOCORE** and STAFF. (Main Bldg. Board Rm.—Capacity 50)
 Follow-up on Hip Bone Blocks for Painful Hips in Adults. Presentation of Cases.
 Secondary Joint Changes Following Burns. (Same Rm.)
 Tuberculosis of the Greater Trochanter of the Femur. Follow-up Study. Complications. Presentation of Cases. (Same Rm.)
 Abduction Hip Splint for Congenital Dislocation of the Hip. Occipitocervicothoracic Fusion. Four-year Follow-up on an Unusual Case of Cervical Pott's Disease Complicated by Paraplegia. (Same Rm.)

LONG ISLAND COLLEGE HOSPITAL

9:00-10:00. *Obstetrics and Gynecology* Operative and Nonoperative Clinics. Clinics and Demonstrations. Members of the Staff. (Surg. Amphitheater—Capacity 100)
 10:00-11:00. *General Surgery* Operative Clinic: Operative Clinics, Demonstrations, Cases and End-Results. **FRED SCHWARTZ** and STAFF. (Same Rm.)

METHODIST HOSPITAL

8:00-10:00. *General Surgery* Operative Clinic. **HAROLD K. BILL**, **SEYMOUR G. CLARK** and STAFF. (Main O.R. 6—Capacity 5)
 8:00-10:00. *Orthopedic Surgery* Operative Clinic. **HENRY P. LAWRE** and STAFF. (Main O.R. Orthopedic Rm.—Capacity 5)
 10:00-12:00. Lunches at the Hospital.
 10:00-12:00. *General Surgery* Nonoperative Clinic: Symposium on Gastric and Duodenal Surgery. **ELMER F. GRAHAM**, Moderator.
 The Peptic Ulcer Problem. **H. K. BILL**. (Nurse's Auditorium—Capacity 300)
 The Value of X Ray in Diagnosis of Peptic Ulcer. **G. W. CHASE**. (Same Rm.)
 The Value of the Gastroscopy in Diagnosis of Peptic Ulcer. **E. A. SUMNER**. (Same Rm.)
 Primary Carcinoma of the Duodenum. **P. A. REIDEN**. (Same Rm.)
 Preoperative and Postoperative Care. **M. HOBBS**. (Same Rm.)
 Our Experience with Subtotal Gastrectomy. **S. G. CLARK**. (Same Rm.)
 Vagotomy for Peptic Ulcer. **E. H. GRIFFIN**. (Same Rm.)
 Report of Unusual Cases. **J. A. THOM**. (Same Rm.)
 Demonstration of Pathology. **J. HORN**. (Same Rm.)
 Demonstration of X Rays. **G. W. CHASE**. (Same Rm.)

CLINICS IN NEW YORK HOSPITALS

Wednesday

BABIES HOSPITAL
 (See Presbyterian Hospital)
 BEEKMAN DOWNTOWN HOSPITAL
 9:30-11:00. *Traumatic Surgery* Nonoperative Clinic.
 Ward Fracture Rounds. **ROBERT H. KROGER** and STAFF. (Wards. Total Capacity 30. In groups 5-6)

11:00-12:00. *Traumatic Surgery* Nonoperative Clinic.
 Sensory Denervation of the Heel for Persistent Pain Due to Old Calcaneal Fracture. **MYRON A. SALLICK**. (2nd Fl. Annex. Capacity 50)
 Indications for Myotomy in Flexor Tendon Injuries.
 LINTNER BLOW. (Same Rm.)

Abdominal Puncture as a Diagnostic Aid in the Acute Abdomen. **STURMUND MAGEE**. (Same Rm.)
General Discussion of Patients Seen on Rounds. **ROBERT H. KENNEDY and STAFF**. (Same Rm.)

BELLEVUE HOSPITAL—FIRST (COLUMBIA UNIVERSITY) SURGICAL DIVISION

8:00—12:00. *Thoracic Surgery* Operative Clinic. **FRANK B. BERRY and STAFF**. (O. R. C & D 5th Fl.—Capacity 10)

BELLEVUE HOSPITAL—SECOND (CORNELL UNIVERSITY) SURGICAL DIVISION

8:30—10:30. *General Surgery* Operative Clinics. **GUILFORD S. DUDLEY and STAFF**. (K & O. R.—Capacity 5)

Abdominopelvic Resection for Carcinoma of Rectosigmoid. **GUILFORD S. DUDLEY**. (O. R. A)

Split Thickness Skin Graft to Arm. **CARLETON CORNELL**. (O. R. B.—Capacity 5)

Subtotal Gastrectomy for Peptic Ulcer. **CRANSTON HOLMAN**. (O. R. C.—Capacity 5)

Thoracolumbar Sympathectomy. **ERNEST W. LAMPE**. (O. R. D.—Capacity 5)

10:30—12:00. *General Surgery* Nonoperative Clinics (C & D Amph.—Capacity 100)

Report on a Series of Esophagogastronomy Cases. **LAURENCE MISCALL**

Report on 17 Cases of Richter's Hernia. **DAVID LYTAL, RAYMOND LUOMAMEN**

Report on 120 Cases of Internal Fixation of Fractures of Neck of Femur. **RAYMOND LUOMAMEN, JOHN PRODDEN**

Split Thickness Grafts in General Surgery. **CARLETON CORNELL**

Report on a Series of Peptic Ulcer Perforations. **S. W. MOORE, ROBERT HENDRICKS**

Report on a Series of 7 Cases of Gastrojejunal Colic Fistula. **HERBERT REIKERT**

12:00—4:30. *Genitourinary Surgery* Operative and Non-operative Clinic. **ROBERT HORTCHINS and HOWARD JACK G. W. DRAVER and GEORGE SLAUGHTER**

GUSTAV HUMPHREYS and JOSEPH REIKERT DEAN MAKOWSKI. (K-6 O. R. Capacity 5)

BELLEVUE HOSPITAL—THIRD (NEW YORK UNIVERSITY) SURGICAL DIVISION

8:00—12:00. *Anesthesia* Operative Clinic. **Anesthesia in Thoracic Surgery**. **E. A. ROVERGONE and STAFF**. (8th Fl. C & D O. R.—Capacity 5)

12:00—5:00. *General* Nonoperative Clinic. **Demonstration Rehabilitation and Physical Medicine for Hemiplegia, Rehabilitation Programs for Hemiplegic Patients**. **GEORGE DRAVER**. (Wards F & G-3, 3rd Fl. F & G Bldg.—Capacity 15)

BETH ISRAEL HOSPITAL

9:00—12:00. *Neurosurgery* Operative Clinic. **SMOXY GROSS and STAFF**. (Neurosurgical O. R. 12th Fl.—Capacity 6)

12:00—5:00. *General Surgery* Operative Clinic. **LEON GINSBURG, SAMUEL STANDARD and STAFF**. (Main O. R., 12th Fl.—Capacity 36)

12:00—5:00. *Bacteriology and Serology* Nonoperative Clinic. **Penicillin and Streptomycin**. **ERICK SELIGMAN**. (3rd Fl., Lecture Rm.—Capacity 30)

FLOWER AND FIFTH AVENUE HOSPITALS

9:00—10:00. *General Surgery* Operative Clinic. **A New Operation for Pilonidal Cyst**. **JOHN HERRLIM**. (Main O. R. 8th Fl.—Capacity 15)

Nonoperative Clinic: Preoperative and Postoperative Care. **LOUIS R. KAUFMAN, JAMES M. WINTZELD and STAFF**. (Auditorium—Capacity 300)

10:00—12:00. *General Surgery* Nonoperative Clinic. **Test for Viability of Bowel**. **JOHN HERRLIM, KURT LAURET, S. THOMAS GLASSER**

Nonoperative Clinic: Intestinal Obstruction. **ROBERT T. CROWLEY**. (Auditorium—Capacity 300)

12:00—4:00. *Orthopedic Surgery* Nonoperative Clinics. **Orthopedic Surgery**. **ANNON H. BUCHANAN**. (Same Rm.)

12:00—4:00. *Fractures* Nonoperative Clinic. **Fracture Treatment—Motion Pictures and End Results—Demonstrations**. **MILTON J. WILSON and STAFF**. (Same Rm.)

12:00—4:00. *Plastic Surgery* Operative Clinic. **Plastic Surgery (Strabismus)**. **DAVID M. MAYER, CLARENCE R. STRAATMAN, JOHN F. FORD**. (Main O. R. 8th Fl.—Capacity 15)

Nonoperative Clinic: End Results. **DAVID M. MAYER, CLARENCE R. STRAATMAN, JOHN F. FORD**. (Nurse's Lecture Rm. 8th Fl.—Capacity 25)

12:00—4:00. *Urology* Nonoperative Clinic. **Teaching Exhibit in Outpatient Department**. **SPRAGUE CARLETON and STAFF**. (O. P. D. 10th St. Entrance—Capacity 25)

Nonoperative Clinic: McGregor Orchiectomy. **L. P. WERNER**. (Room A-41—Capacity 18)

GOLDWATER MEMORIAL HOSPITAL—THIRD SURGICAL DIVISION

9:00—10:00. *General Surgery* Operative Clinic. **HOWARD BARBER and STAFF**. (Adm. Bldg. Main O. R. 3rd Fl.—Capacity 30)

9:00—11:30. *Geriatric Surgery* Nonoperative Clinics. **Refrigeration in Clinical Surgery**. **W. F. RUGGERS**

Primary Closure in Amputations of Lower Extremity. **M. J. TOMAS**

Herniorrhaphy in the Aged. **M. STANLEY BROWN**

Arteriotomy. **NEED SCHENATERRON**

Peritonitis in the Aged. **T. C. CASE**

11:30—12:00. *Geriatric Surgery* Nonoperative Clinic. **Ward Rounds**. (C 21 and 22)

12:00—4:30. *Geriatric Surgery* Nonoperative Clinics. **The Treatment of Varicose Ulcers by Ligation of Femoral Vein**. **LEO KENNEDY**. (North Conference Rm. and Fl. Between C and D Pavilion—Capacity 50)

Pandiculitis in the Aged. **HEINRY DOUGLASS**. (Same Rm.)

Prostatectomy in the Complicated Case. **SAMUEL S. BERENSON**. (Same Rm.)

Interesting Urological Conditions in the Aged. **GEORGE SLAUGHTER**. (Same Rm.)

Intravenous Procaine in Surgery. **MILTON OFFENHEIM**. (Same Rm.)

Arteriography. **EDMOND TORTORA**. (Same Rm.)

Combined Lumbar Sympathectomy and Vein Ligation for Peripheral Vascular Disease. **B. SHAPIROFF**. (Same Rm.)

4:30—5:30. *Geriatric Surgery* Nonoperative Clinic. **Forum on Surgical Investigation by Postgraduate Class of Surgery**. (Same Rm.)

HARLEM EYE AND EAR HOSPITAL

8:00—9:00. *Otolaryngology* Operative Clinic. **Tonsillectomies with Medial tonsil enucleator**. **C. B. MIZNER, E. GLASSBERG and STAFF**. (Tonnal O. R.—Capacity 5)

9:00—10:00. *Ophthalmology and Otorhinolaryngology* Operative Clinic. **Major Eye, Ear, Nose and Throat Surgery**. **A. HEATHINGTON**. (Major O. R.—Capacity 5)

10:00—11:00. *Otorhinolaryngology* Demonstration. **Demonstration of Ear, Nose and Throat Cases**. **C. B. MIZNER and STAFF**. (E. N. T. Clinic—Capacity 20)

- 1200-1300. *Otolaryngology* Operative Clinic—Rhinoplasty Surgical Case. H. SARIM (Major O.R.—Capacity 5)
 1200-2000. *Ophthalmology* Operative Clinic Eye Surgery C. B. MEDOW, P. MULLER (Major O.R.—Capacity 5)

HARLEM HOSPITAL

- 900-1200. *General Surgery* Nonoperative Clinic Symptom on Lymphogranuloma and Rectal Stricture. Ward Rooms. L. T. WARDER, J. G. LEVY and STAFF (Ward 5th Women Pavilion—Capacity 5)
 100-500. *Gynecology* Synopostum. H. C. FAIR, P. M. MURRAY, and STAFF
 Operative Clinic 1. Gynecological Surgery (Gyn. O.R. 4th Fl. Women's Pavilion—Capacity 8)
 Nonoperative Clinics () Management of Postabortal Infection, (b) Management of Recurrent Salpingitis, (c) Management of Pyometra Complicating Fibroid with End Results. (Conference Rm. 4th Fl. Women's Pavilion—Capacity 8)

HOSPITAL FOR JOINT DISEASES

- 900-930. *Orthopedic Surgery* Operative Clinic Nerve Resection for Painful Arthritis of Hip Joint. ISAAC ZADK. (Surg. Amphitheater—Capacity 50)
 930-1200. *Genitourinary Surgery* Operative Clinic Hemorrhoids, Flatula-In-ano Benign Adenoma of Rectum, Pilonidal Cyst. Nonoperative Clinic Lymphogranuloma Venereum. HARRY GOLDMAN. (Small O.R.—Capacity 5)
 1200-1300. *Genitourinary Surgery* Operative Clinic Surgery of the Kidneys, Ureter and Bladder PAUL ASCHMEHL. (Surg. Amphitheater—Capacity 50)

HOSPITAL FOR SPECIAL SURGERY

- 830-1200. *Orthopedic Surgery* Operative Clinic Children's Service. PHILIP D. WILSON and STAFF (Male O.R.—Capacity 5)
 900-1200. *Orthopedic Surgery* Nonoperative Clinic General Surgical Problems. F. BECKMAN, R. V. GRACE, B. L. COLEY and STAFF (Lecture Hall—Capacity 50)
 1200-1300. *General and Plastic Surgery* Nonoperative Clinic. General Surgical Problems and Plastic Surgery F. BECKMAN and STAFF (Same Rm.)

LENOX HILL HOSPITAL

- 900-1200. *General Surgery* Operative Clinic. OTTO C. PICHAARD and STAFF (O.R. and 3—Capacity each 15)
 1200-1300. *General Surgery* Nonoperative Clinic. Experiences in Vagotomy for Peptic Ulcer. JAMES R. DONALDSON (Einhorn Auditorium—Capacity 450)
 1300-1400. *Thoracic Surgery* Nonoperative Clinic Late Results Following Pneumectomy and Lobectomy in Bronchiectasis, Cystic Disease of the Lung and Pulmonary Abscess. HERBERT C. MAYER, WALTER FENCHE. (Same Rm.)

LYING-IN HOSPITAL

(See New York Hospital)

MANHATTAN EYE, EAR AND THROAT HOSPITAL

- 900-1200. *Ophthalmology* Nonoperative Clinic. Demonstration of Anisokonia Clinic. A. LOREZ. (1st Fl. Rear—Capacity 5)
 900-1200. *Ophthalmology* Operative Clinic: Plastic Operations of Eye. BEROM SMITH. (Eye O.R. 6th Fl.—Capacity 5)

- 900-1200. *Otolaryngology* Demonstration. Postoperative Cases. M. F. JONES, R. J. BEHRETT (Jones Clinic and 11—Capacity 24)
 930-1200. *Ophthalmology* Demonstration, Glaucoma Clinic. Late Results of Glaucoma Surgery F. L. P. KOCH. (East Eye Clinic 1st Fl.—Capacity 24)
 1000-1200. *Ophthalmology* Demonstration. Corneal Grafting Technique on Rabbits. H. M. KATZ. (Eye Bank Lab. 10th Fl.—Capacity 5)
 000-1200. *Otolaryngology* Operative Clinic and Demonstration. Operation for Polypoid Sinusitis and Demonstration of Postoperative Cases. A. NICO. (1st Fl. O.R.—Capacity 5)
 100-1200. *Ophthalmology* Demonstration. Corneal Grafting Technique. Corneal Research Laboratory R. T. LAYTON, H. M. KATZ. (Eye Bank Lab. 10th Fl.—Capacity 5)
 120-1200. *Otolaryngology* Bronchoscopic Clinic. Diagnosis and Treatment. D. S. CURWOOD. (Bronche. Clinic 3rd Fl.—Capacity 5)
 1200-1300. *Otolaryngology* Operative Clinic: Frenotomy Operation. M. F. JONES. (O.R. 6th Fl.—Capacity 5)
 1200-1300. *Ophthalmology and Otolaryngology* Demonstration. Allergy in Ophthalmology. Allergy in Otolaryngology. Demonstration of Cases and Testing Technique. A. A. ECKHART, A. B. PAGE. (Conference Rm.—Capacity 50)
 120-1200. *Otolaryngology* Operative Clinic. Tonsil Surgery. WILLIAM H. TURNLEY. (O.R. 7th Fl.—Capacity 5)
 100-1200. *Ophthalmology* Operative Clinic. Cataract Surgery. D. H. WENZEL. (Eye O.R. 6th Fl.—Capacity 5)
 1200-1300. *Ophthalmology* Demonstration. Eye Pathology. Demonstration Microscopic Sections. JOSEPH LAYAL. (Eye Path. and 11—Capacity 50)

MEMORIAL HOSPITAL

- 800-1200. *Tumor Surgery* Operative Clinic. FRANK E. ADAMS, G. E. BOWLEY, B. L. COLEY, A. L. DEAS, V. F. MAXWELL, DAVES MARTIN, GEORGE T. PAGE, G. H. TWOMBLY, W. L. WATSON. (O.R. A—Capacity 5, O.R. B—Capacity 15, O.R. C—Capacity 7, O.R. D—Capacity 7, O.R. E—Capacity 7)
 100-1200. *Tumor Surgery* Nonoperative Clinic. Stages. Kettering Institute. Biochemical Changes in Patients with Cancer
 Altered Steroid Excretion of Patients with Cancer and Other Diseases. K. DOBNER, S. LIEBERMAN (Auditorium—Capacity 450)
 Altered Carbohydrate Metabolism in Patients with Gastric Cancer. N. F. YOUNG, F. HONORBERGER. (Same Rm.)
 The Interpretation of Protein Determinations. M. L. PETERMAN, N. F. YOUNG, K. HONORBERGER. (Same Rm.)
 Altered Protein Metabolism and the Clinical Implications of the Systemic Disorder in Patients with Gastric Cancer. F. HONORBERGER, N. F. YOUNG, E. C. KETTERING JR. (Same Rm.)
 The Modern Orientation of Clinical Cancer Research: A Discussion of the Preceding Papers. C. P. RUSSELL. (Same Rm.)
 Revised Hayes Martin Clinic. (Same Rm.)
 Castration in Carcinoma of Male Breast. N. E. TAYLOR. (Same Rm.)
 120-1300. *Tumor Surgery* Nonoperative Clinic: Follow up Clinics in Cancer of the Uterus. G. H. TWOMBLY. (Auditorium—Capacity 450)

3:00-4:00. *Tumor Surgery* Nonoperative Clinic. The Conduct of End Results in Early Cancer Detection Clinic. ELIAS L'ESPÉRANCE. (Same Rm.)

METROPOLITAN HOSPITAL

- 9:00-10:00. *General Surgery* Non-Operative Clinic. Intestinal Obstruction. CHARLES A. HALBERSTADT, ROBERT T. CROWLEY (Conference Rm.—Capacity 60)
- 10:00-12:00. *General Surgery* Operative Clinic. Colon Surgery. HAROLD E. CLARK. (Same Rm.) Intestinal Intubation. WALTER L. MEISSENER. (Same Rm.)
- 2:00-4:00. *Thoracic Surgery* Operative Clinic. Value of Cavernostomy in Tuberculosis (2 Operations). SAMUEL A. THOMPSON and STAFF. (Main O.R. 1—Capacity 30)
- 4:00-5:00. *Neurosurgery* Operative Clinic. Nerve Suture Cases. THOMAS I. HOEK, IGOR OLJENICK and STAFF. (Main O.R. 2—Capacity 15)

MONTEFIORE HOSPITAL

- 10:00-12:00. *General Surgery* Nonoperative Clinic. Results of Treatment of Hydrocephalus by Choroid Plexectomy. LEO DAVIDOFF. (Social Hall—Capacity 200)
- 2:00-5:00. *General Surgery* Operative Clinic. LEO DAVIDOFF. (O.R.—Capacity 10)
- 5:00-7:00. *Ophthalmology* Ophthalmological Service. Vitreous Transplantation. S. GARTNER, B. PRITZELT. (Social Hall—Capacity 200)
- Visual Field Studies in Neurosurgery. M. CHAMLER. (Same Rm.)
- Electroretinography. E. BILLET
- Modified Tarsorrhaphy for High Degrees of Exophthalmos. S. GARTNER, M. CHAMLER
- Cataract Surgery in Young Diabetics. A. I. LARSEN.

MOUNT SINAI HOSPITAL

- 8:30-10:00. *Thoracic Surgery* Operative Clinic Operation for Patent Ductus Arteriosus. ARTHUR S. W. TOUROFF. (Surg. Amph.—Capacity 100)
- 10:00-12:00. *Thoracic Surgery* Nonoperative Clinic. Intramuscular Heparin (Concentrated) Therapy in the Prevention of Post-Operative Thrombosis and Embolism. HAROLD NEUBER. (Surg. Amph.—Capacity 100)
- Technique of Operation for Clotted Hemothorax (Motion Picture Demonstration). (Same Rm.)
- Results of Operative Treatment of Traumatic Thoracic Lesions in Civilian Practice. ARTHUR S. W. TOUROFF. (Same Rm.)
- Operative Results in Pediatric Surgery. ERNEST E. ABRAHAM. (Same Rm.)
- Results of Surgical Treatment of Perforation of the Esophagus. EDWARD A. JENKINS. (Same Rm.)
- Results of Conservative Surgical Treatment of Chronic Pulmonary Abscess. IRVING A. SAROT. (Same Rm.)
- Late Results in Pulmonary Resection for Carcinoma of the Lung. (Same Rm.)
- 2:00-5:00. *Ophthalmology* The Surgical Treatment of Glaucoma. JOSEPH LAVAL. (Same Rm.)
- Operative and Nonoperative Clinic. Operated Cases. HENRY MINNEY, JOSEPH LAVAL, DAVID WEXLER. (Same Rm.)

NEW YORK EYE AND EAR INFIRMARY

- 10:00-12:00. *Otolaryngology* Nonoperative Clinic. Frenotomy—Preoperative and Follow-up. J. M. SMITH. (Clinic Rm.—Capacity 20)
- Otolaryngology* Plastic Surgery Preoperative and Follow-up. JAY D. WHITMAN. (Same Rm.)

2:00-5:00. *Otolaryngology* Operative Clinic Frenotomy Operation. J. M. SMITH. (Ear O.R.—Capacity 5)

Otolaryngology Operative Clinic—Plastic Surgery. JAY D. WHITMAN. (Same Rm.)

5:00-7:00. *Ophthalmology* Nonoperative Clinic. Indications for Surgical Interference. W. EDGINGTON and H. ELWYN and ASSOCIATES. (Clinic Rm.—Capacity 30)

The Follow-up on Plastic Surgery with Discussion of Further Steps. W. HUGHES, J. COLE and ASSOCIATES. Operative Clinic. Surgical Demonstration with Emphasis on Cataract and Glaucoma Surgery. C. BEERS and H. ROMANOW and ASSOCIATES. (Eye O.R.—Capacity 10)

X Rays and Localization. IRVING SCHWARTZ. The routine clinics of the New York Eye and Ear Infirmary will be held as usual during this period, all Fellows of the American College of Surgeons are cordially invited to attend.

NEW YORK HOSPITAL

- 9:00-11:30. *Neurosurgery* Nonoperative Clinic Symposium Conducted by BROWN S. RAY. Surgical Relief of Intractable Pain of the Head and Neck. HENRY PARSONS. (Room F-650—Capacity 70)
- Ondiographic Study of Sensory Pathways. Evidence of Bilateral Conduction. CHARLES BERRY, RICHARD KARL, JOSEPH C. HENRY. (Same Rm.)
- Alterations in Visceral Sensation After Thoracolumbar Sympathectomy. CHARLES L. NEILL. (Same Rm.)
- Induced Mechanical Stresses in the Analysis of Headache Mechanisms and the Diagnosis of Intracranial Tumors. E. CHARLES KUNTZ. (Same Rm.)
- Sympathetic Supply to the Lower Extremities. ARTHUR D. CONSOLE. (Same Rm.)
- On the Nature of Hyperalgesia. HAROLD G. WOLFF, JAMES D. HARDY, HELEN GOODKILL. (Same Rm.)
- Intracranial Aneurysms. BRIDGSON S. RAY. (Same Rm.)
- 9:00-12:00. *General Surgery* Operative Clinic. General Surgery. FRANK GLICK and STAFF. (10th Fl. O.R.—Capacity 120)
- Nonoperative Clinics. Follow up Study of Treatment of Peptic Ulcer. WILLIAM A. COOPER. (College Auditorium, Rm. B-601—Capacity 350)
- Bleeding Peptic Ulcer. CHAMBERMAN HOLMAN. (Same Rm.)
- Diagnosis of Stomach Lesions. WILLIAM A. COOPER. (Same Rm.)
- Gastrojejunocolic Fistula. E. COOPER PERSON. (Same Rm.)
- Carcinoma of the Head of the Pancreas. GARDNER CHILD. (Same Rm.)
- Esophagoplastomy—Follow-up of Cases. WILLIAM A. BARRETT. (Same Rm.)
- 2:00-5:00. *Otolaryngology* Operative Clinic. Surgery of the Paranasal Sinuses. SAMUEL F. KELLY. (10th Fl. O.R.—Capacity 30)

NEW YORK HOSPITAL LYING-IN HOSPITAL

- 9:00-12:00. *Obstetrics and Gynecology* Operative Clinics. Tubal Plastic Operation for the Relief of Sterility. J. RANDOLPH GIFFERT. (Gyn. O.R., 2 Rms. Capacity 50)
- Gynecological Operations. R. GORDON DOUGLAS. (Same Rm.)
- Forceps Demonstration. JAMES A. HARRAR. (Same Rm.)
- 2:00-5:00. *Obstetrics and Gynecology* Nonoperative Clinics. Evaluation of Prophylactic Chemotherapy in Cesarean Section. R. GORDON DOUGLAS, ROBERT LAUDERMAN. (Lecture Rm.—Capacity 100)

- Labor and Delivery Following Cesarean Section. ARTHUR WILSON. (Same Rm.)
- Pregnancy Following Salpingostomy J RANDOLPH GUYBERT. (Same Rm.)
- Studies on Pain During Labor CARL T JAVERT JAMES HARDY. (Same Rm.)
- The Conservative Treatment of Endometriosis. ARTHUR V GREELLY. (Same Rm.)
- The Treatment of Massive Hemorrhage. JOHN T COLL. (Same Rm.)
- Vaginal Swears in Early Diagnosis of Carcinoma. GEORGE PAPANTOLOS. (Same Rm.)

NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL

- 8 30-100. *Orthopedic Surgery* Operative Clinic. ALAN DE FOREST SMITH and STAFF (O.R. 1 & 2—Capacity 12)
- 30-400. *Orthopedic Surgery* General Orthopedic Clinic. HALFORD HALLOCK and STAFF (7th Floor Assembly Room—Capacity 30).

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL

- 8 30-300. *Plastic Surgery* Operative Clinic. GUSTAVE AUDINET. (O.R. 2—Capacity 1)
- 30-120. *General Surgery* Nonoperative Clinic Gall Bladder Disease, Common Duct Disord. R. FRANK LEE CARTER. (Erdmann Auditorium—Capacity 25)
- 1 00-500. *General Surgery* Operative Clinic. H. E. CLARK. (O.R. —Capacity 1)
- Operative Clinic C. G. HERR. (Surg. Amph.—Capacity 50)
- 100-500. *Gynecology* Operative Clinic. M. N. HYMAN. (O.R. 5—Capacity 1)

PRESBYTERIAN HOSPITAL

- 8 00-100. *General Surgery* Operative Clinics
- Surgery of the Breast. CURTIS D. HAAGENSEN and STAFF (Balcony FL. 9, Main O.R. D-G—Capacity each 6)
- Surgery of the Stomach. RUDOLPH N SCHULDMYER, EDWARD L. HOWES. (Same Rm.)
- Portacaval Anastomosis. ARTHUR H. BLAKEMORE. (Same FL O.R. C—Capacity 6)
- 1 00-400. *General Surgery* Nonoperative Clinic: Certain Essential Features Suggested by 30 Year Follow-up in Carcinoma of the Breast. HUGH ADAMS-CRAWFORD. (McCook Amph., 8th FL—Capacity 142)
- The Relation of Chronic Cystic Disease to Carcinoma of the Breast. ARTHUR PURDY STOUT. (Same Rm.)
- The Problem of Early Diagnosis in Carcinoma of the Breast. CURTIS D. HAAGENSEN. (Same Rm.)
- Röntgenotherapy of Carcinoma of the Breast in Non-operated Cases and as Preoperative and Postoperative Treatment. MAURICE LEECH. (Same Rm.)
- Surgery Versus Radioth. in Carcinoma of the Breast. CURTIS D. HAAGENSEN. (Same Rm.)

PRESBYTERIAN HOSPITAL BABIES HOSPITAL

- 9 00-100. *General Surgery* Operative Clinic. MICHIGAS OF THE STAFF (O.R. 1 & 2 9th FL—Capacity 5 each)
- 100-200. *General Surgery* Nonoperative Clinic The Surgical Treatment of Cystic Heart Disease. GEORGE H. HONIGSMAN. (Amph. 4th FL—Capacity 15)
- 100-400. *General Surgery* Nonoperative Clinic: Roentgen Findings in Intestinal Obstruction of the New born. JOHN CARTER. (Same Rm.)

- Treatment of Acute Hematogenous Oostomyelitis Comparison of Cases Treated with and without Penicillin Follow-up. EDWARD B. SELBY. (Same Rm.)
- End Results in Operations for Undescended Testicle. EDWARD N. GOODMAN. (Same Rm.)
- Inguinal Hernia in Infancy and Childhood. Indications for Operation in Infancy F. Bow-up. JOHN M. FORD. (Same Rm.)

PRESBYTERIAN HOSPITAL

THE INSTITUTE OF OPHTHALMOLOGY

- 9 00-12 00. *Ophthalmology* Nonoperative Clinic: External Diseases of the Eye. JOHN HUGHES DUNDEE and STAFF (Lecture Rm. 7th FL Eye Inst.—Capacity 40)
- 1 00-4 00. *Ophthalmology* Operative Clinic: Surgery of the Extraocular Muscles and Intracocular Operations JOHN HUGHES DUNDEE and STAFF (O.R. Eye Inst.—Capacity 15)
- Surgical Procedures in Glaucoma and Cataract. ALGER MOY BEVERLY RIDGE and STAFF. (Same Rm.)

PRESBYTERIAN HOSPITAL

SECTION ON OTOLARYNGOLOGY

- 100-200. *Otolaryngology* Nonoperative Clinic: Hearing Aid Fitting. MARY HEDGECOCK. (Rm. 1, 1st FL Vanderbilt Clinic—Capacity 30)
- Fenestration Follow-up. FRANK ALTMAN. (Rm. 124, 1st FL Vanderbilt Clinic—Capacity 30)
- Follow-up of Cases of Bilateral Abductor Paralysis of the Larynx. DEGRAAF WOODMAN. (Same Rm.)
- 30-300. *Otolaryngology* Operative Clinic: Endoscopy GEORGE BRIGHTON. (ENT O.R. A and B—Capacity 6)
- Fenestration. DEGRAAF WOODMAN. (Same Rm.)

PRESBYTERIAN HOSPITAL

SLOANE HOSPITAL FOR WOMEN

- 9 00-10 30. *Obstetrics and Gynecology* Operative Clinic: Repair of Cystocele, Rectocele and Pelvic Floor. B. P. WARREN. (O.R. 7th FL—Capacity 30)
- 100-12 00. *Obstetrics and Gynecology* Operative Clinic: Operation for Vesical Incontinence JOHN H. BOTS. (Same Rm.)
- 100-300. *Obstetrics and Gynecology* Nonoperative Clinic: Surgical Problems in Sterility CHARLES L. BIXTON. (Lecture Rm. 12th FL—Capacity 40)
- 3 00-4 00. *Obstetrics and Gynecology* Nonoperative Clinic: Interpretation of Endometrial Biopsy E. T. LARLE. (Same Rm.)
- 4 00-5 00. *Obstetrics and Gynecology* Nonoperative Clinic: The Possible Carcinogenic Effect of Estrogens S. GUYER. (Same Rm.)

PRESBYTERIAN HOSPITAL

SQUER UROLOGICAL CLINIC

- 9 00-1 00. *Genito-urinary Surgery* Nonoperative Clinic: Sulfonamide Mixtures in the Treatment of Genito-urinary Disease HARRY SANDER. (McCook Amphitheater 8th FL—Capacity 14)
- The Study of the Effect of Streptomycin on Renal Tuberculosis. Preliminary Report. JOHN K. LARSON. (Same Rm.)
- Pathological Classifications of Adrenal Tumors. MARY M. MILLER. (Same Rm.)
- Problems Encountered in the Diagnosis and Treatment of Congenital Anomalies of the Urinary Tract in Infants. JOHN N. ROBINSON CHARLES T. HAZARD. (Same Rm.)

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS

2:00-4:00. **Genitourinary Surgery** Operative Clinic. Surgical Operations. GEORGE F. CARLIS, GEORGE W. FIAT and STAFF (Main O R 19, Rm. C and D—Capacity 35)
 Exhibit on Cystoscopic Equipment (Rm 310, Hosp. 10th FL—Capacity 35)
 Exhibit of Urological Pathology Department (Rm 310, 15th FL, Phys. & Surg. Bldg—Capacity 35)
PRESBYTERIAN NEW YORK ORTHOPEDIC HOSPITALS

9:00-12:00. **Fractures and Traumatic Surgery** Operative Clinic. FRANK R. STUART, STAFF (Main O R 19th FL—Capacity 8)
 1:30-4:00. **Fractures and Traumatic Surgery** Nonoperative Clinic. Shoulder Girdle Injuries and Recurrent Shoulder Dislocations with Follow up Results. HARRY L. McLAUGHLIN (Rm 417 16th FL, Phys. & Surg. Bldg—Capacity 100)
 Results of Open and Closed Treatment of Pott's Fractures. VERNER H. STURGEON (Same Rm.)

ROOSEVELT HOSPITAL

9:00-12:00. **General Surgery** Operative Clinic. Surgical Treatment of Lesions of the Colon Subtotal Colectomy for Ulcerative Colitis. ROUNDS and STAFF (O R 13)
 12:00-1:00. **Gynecology** Operative Clinic. Gynecology Patients. HARRY W. CARR and STAFF (O R 13)
 1:00-2:00. **General Surgery** Operative Clinic. Cancer of the Breast. Radical Mastectomy. ROUNDS, Presentation of Cases and Illustration of Late Results. WILLIAM C. WHITE and STAFF (O R 13—Total capacity 50)
 2:00-4:00. **Gynecology** Nonoperative Clinic. The Early Results of Malignancies of the Female Pelvic Organs. Results of the Uterus, etc. (Conference Room 1—Capacity 50)

2:00-4:00. **General Surgery** Nonoperative Clinic. Surgical Treatment of Lesions of the Colon Sequelae, Complications and Late Results of the Surgical Treatment of Ulcerative Colitis. (Motion Pictures of Cases of Ileostomy and Colectomy Presentation of Cases Showing Late Results) HARRY W. CARR (Same Rm.)
 The Late Results of Carcinoma of the Thyroid Gland. JAMES F. THOMSON (Same Rm.)
 Presentation of Cases Illustrating Interesting and Unusual Fractures (Illustrations) WILLIAM H. CARR (Same Rm.)
 Nonunion in Fractures of the Femoral Neck, Case Presentations (Illustrations) M. BECKETT HOWARTH (Conference Rm. 2—Capacity 50)

ST LUKE'S HOSPITAL

8:30-1:00. **Genitourinary Surgery** Operative Clinic. Urologic Surgery. GEORGE HOEN and STAFF (Lyle O R—Capacity 15)
 11:00-1:00. **Orthopedic Surgery** Clinical Demonstration Pathological Demonstration of Internal Derangement of Knee Joint with End Results. DAVID BOWEN and STAFF (Staff Conference Rm—Capacity 60)
 Trochanteric Fractures of Femur Treatment and End Results. FRED THOMSON (Same Rm.)
 2:00-4:00. **Genitourinary Surgery** Clinical Demonstrations Follow-up on War Paraplegia. BORIS PETEROFF and STAFF (Same Rm.)

Follow-up on Vocal Neck Obstructions to Abdomino-perineal Resection. JAMES WALSH (Same Rm.)
 Results of Transurethral Resection. GEORGE HOEN (Same Rm.)
 Combined Treatment of Transverse Resection and Radiotherapy of Bladder Tumors. CRAIG COATES (Same Rm.)
 Renal Rickets. ALLEY (Same Rm.)
 Bilateral Hydronephrosis and Hydroureter. GEORGE HOEN (Same Rm.)

ST VINCENT'S HOSPITAL

9:00-12:00. **General Surgery** Operative Clinic. General Surgery. RAYMOND F. SULLIVAN and ASSOCIATES (O R A and B—Capacity 10 each)
 9:00-12:00. **Neurosurgery** Operative and Follow-up Study of the Treatment of Painful Phantom Limb by Removal of Sensory Cortex. C. G. GUTTERERRE (O R C—Capacity 10)
 12:00-1:00. **General Surgery** Operative and Nonoperative Clinics. Surgery of Gastric and Duodenal Ulcer. GEORGE R. STUART, FRANK J. MCGOWAN, J. P. BROCKMAN (O R D—Capacity 10)
 1:00-2:00. **General Surgery** Nonoperative Clinic. Round Table Discussion. Acute Pancreatitis. CONSTANTINE J. MAGUIRE (Nurse's Auditorium—Capacity 150)
 Reconstruction of Common Bile Duct. RAYMOND P. SULLIVAN, JOHN C. MURPHY (Same Rm.)
 Follow-up Report on 100 Cases of Fracture of Both Bones of the Leg. EDWARD V. DRENNER, F. R. EASTON (Same Rm.)
 2:00-4:00. **Pathology** Theme Culture Demonstration of Malignancy. Display of Fresh Pathological Material. Display and Demonstration of System Diseases by histochromic Stains. A. ROTTINO and ASSOCIATES (Nurse's Home Lab—Capacity 50)

SLOWE HOSPITAL FOR WOMEN

(See Presbyterian Hospital)

U. S. MARINE HOSPITAL

(STATEN ISLAND)

10:00-12:00. **General Surgery** Nonoperative Clinics. Reconstruction Surgery of Face Deformities—Traumatic. Discussion and Case Presentation. Reconstruction of Hand—Discussion and Case Presentation (Doctor's Staff Rm.—Capacity 75)
 12:00-1:00. **Obstetrics and Gynecology** Operative and Nonoperative Clinics. Regional Block in Obstetrics. EDWARD C. L. HENNER (GU O R—Capacity 10)
 1:00-2:00. **Obstetrics and Gynecology** Operative Clinics. Luncheon at the Hospital. Hysterectomy. Vaginal Plastic. GEORGE HOEN (Surg. O R—Capacity 50)
 2:00-4:00. **Ophthalmology** Nonoperative Clinic. Injuries of the Eye with Case Presentation. J. B. PERLES and STAFF (Doctor's Staff Rm.—Capacity 75)

VETERANS ADMINISTRATION HOSPITAL

9:00-12:00. **General Surgery** Operative Clinic. JOHN F. SULLIVAN, CARLOS WELLS (Bldg D 2 Rm. 12th FL—Capacity 50)
 9:00-12:00. **Thoracic Surgery** Operative Clinic. RICHMOND MOORE, WALTER CRANDALL, AARON HINDENLITZ (Bldg D 12th FL 1 Rm.—Capacity 10)

Labor and Delivery Following Cesarean Section. ARTHUR WILLSON (Same Rm.)
 Pregnancy Following Salpingostomy J. RANDOLPH CLEVELAND (Same Rm.)
 Studies on Pain During Labor. CARL T. JAVERT, JAMES HARDY (Same Rm.)
 The Conservative Treatment of Endometriosis. ARTHUR V. GREILEY (Same Rm.)
 The Treatment of Massive Hemorrhage. JOHN T. COLE (Same Rm.)
 Vaginal Senars in Early Diagnosis of Carcinoma. GEORGE PAPANICOLAOU (Same Rm.)

NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL

- 8:30-10:00. *Orthopedic Surgery* Operative Clinic. ALAN DE FOREST SMITH and STAFF (O.R. 1 & 2—Capacity 12)
 10-12:00. *Orthopedic Surgery* General Orthopedic Clinic. HALLOW HALLLOCK and STAFF (7th Floor Assembly Room—Capacity 30)

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL

- 8:30-12:00. *Plastic Surgery* Operative Clinic. GUYRAVE AUSTIN (O.R. 2—Capacity 5)
 10-12:00. *General Surgery* Nonoperative Clinic Gall Bladder Disease, Common Duct Disord. R. FRANKLIN CARTER, (Erdmann Auditorium—Capacity 5)
 10-5:00. *General Surgery* Operative Clinic H. F. CLARK (O.R. 1—Capacity 5)
 Operative Clinic. C. G. HAYD (Surg. Amph.—Capacity 30)
 10-5:00. *Gynecology* Operative Clinic. M. N. HARRIS (O.R. 3—Capacity 5)

PRESBYTERIAN HOSPITAL

- 8:00-10:00. *General Surgery* Operative Clinic
 Surgery of the Breast. CURTIS D. HAAGENBOEK and STAFF (Bakony Fl. 9, Main O.R. D-G—Capacity each 6)
 Surgery of the Stomach. RUDOLPH N. SCHULLINGER, EDWARD L. HOWES (Same Rm.)
 Thoracic Anomalies. ARTHUR H. BLANKENHORN (Same Fl. O.R. C—Capacity 16)
 10-4:00. *General Surgery* Nonoperative Clinic Certain Essential Features Suggested by 30 Year Follow-up in Carcinoma of the Breast. HUGH ADCHINSON (McCosh Amph., 8th Fl.—Capacity 145)
 The Relation of Chronic Cystic Disease of the Carcinoma of the Breast. ARTHUR PURDY SPOUT (Same Rm.)
 The Problem of Early Diagnosis in Carcinoma of the Breast. CURTIS D. HAAGENBOEK (Same Rm.)
 Roentgenotherapy of Carcinoma of the Breast in Non-operated Cases and as Preoperative and Postoperative Treatment. MAURICE LERZ (Same Rm.)
 Surgery Versus Radiation in Carcinoma of the Breast. CURTIS D. HAAGENBOEK (Same Rm.)

PRESBYTERIAN HOSPITAL BABIES HOSPITAL

- 9:00-10:00. *General Surgery* Operative Clinic. MEMBERS OF THE STAFF (O.R. 1 & 2, 6th Fl.—Capacity 5 each)
 10-12:00. *General Surgery* Nonoperative Clinic: The Surgical Treatment of Cyanotic Heart Disease. GEORGE H. HUMPHREYS (Amph. 4th Fl.—Capacity 75)
 10-4:00. *General Surgery* Nonoperative Clinic: Roentgen Findings in Intestinal Obstruction of the New born. JOHN CARTER (Same Rm.)

Treatment of Acute Hematogenous Osteomyelitis: Comparison of Cases Treated with and without Penicillin Follow-up. EDWARD B. SELF (Same Rm.)
 End-Results in Operations for Undescended Testis. EDWARD N. GOODMAN (Same Rm.)
 Inguinal Hernia in Infancy and Childhood. Indications for Operation in Infancy Follow-up. JOSE M. FERRER (Same Rm.)

PRESBYTERIAN HOSPITAL

THE INSTITUTE OF OPHTHALMOLOGY

- 9:00-12:00. *Ophthalmology* Nonoperative Clinic: External Diseases of the Eye. JOHN HUGHES DODDINGTON and STAFF (Lecture Rm. 7th Fl. Eye Inst.—Capacity 40)
 10-4:00. *Ophthalmology* Operative Clinic: Surgery of the Extraocular Muscles and Intraocular Operations. JOHN HUGHES DODDINGTON (O.R. Eye Inst.—Capacity 5)
 Surgical Procedures in Glaucoma and Cataract. ALGER MOY BEVERLY REESE and STAFF (Same Rm.)

PRESBYTERIAN HOSPITAL

SECTION ON OTOLARYNGOLOGY

- 10:00-12:00. *Otolaryngology* Nonoperative Clinic: Hoarseness and Flitting. MARY HODGSON (Rm. 213, 1st Fl. Vanderbilt Clinic—Capacity 30)
 Fertilization Follow-up. FRANK ALTMAN (Rm. 213, 1st Fl. Vanderbilt Clinic—Capacity 30)
 Follow-up of Cases of Bilateral Abductor Paralysis of the Larynx. DEBRA WOODMAN (Same Rm.)
 10-5:00. *Otolaryngology* Operative Clinic: Endoscopy. GEORGE BRIDGTON (E.N.T. O.R. A and B—Capacity 6)
 Fertilization. DR. GRAY WOODMAN (Same Rm.)

PRESBYTERIAN HOSPITAL

SLOANE HOSPITAL FOR WOMEN

- 9:00-10:00. *Obstetrics and Gynecology* Operative Clinic: Repair of Cystocele, Rectocele and Pelvic Floor. B. P. WATSON (O.R. 7th Fl.—Capacity 30)
 10:00-12:00. *Obstetrics and Gynecology* Operative Clinic: Operation for Vesical Incontinence. JOHN H. BORN (Same Rm.)
 10-3:00. *Obstetrics and Gynecology* Nonoperative Clinic: Surgical Problems in Sterility. CHARLES L. BROWN (Lecture Rm. 7th Fl.—Capacity 40)
 10-4:00. *Obstetrics and Gynecology* Nonoperative Clinic: Interpretation of Endometrial Biopsy. E. T. FOWLE (Same Rm.)
 4:00-5:00. *Obstetrics and Gynecology* Nonoperative Clinic: The Possible Carcinogenic Effect of Estrogens. S. GREENBERG (Same Rm.)

PRESBYTERIAN HOSPITAL

SOUTHERN UROLOGICAL CLINIC

- 9:00-10:00. *Genitourinary Surgery* Nonoperative Clinic: Sulfonamide Mixtures in the Treatment of Genitourinary Disease. HARRY SCHICK (McCosh Amphitheater 8th Fl.—Capacity 4)
 The Study of the Effect of Streptomycin on Renal Tuberculosis. Preliminary Report. JOHN K. LATTIN (Same Rm.)
 Pathological Classifications of Adrenal Tumors. MILES M. MULLOWN (Same Rm.)
 Problems Encountered in the Diagnosis and Treatment of Congenital Anomalies of the Urinary Tract in Infants. JOHN N. ROBINSON CHARLES T. HARRIS (Same Rm.)

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS

1200-4200. *Genitourinary Surgery* Operative Clinic: Sur-
gical Operations GEORGE F. CARILL, GEORGE W.
FISKE and STAFF (Balcony Fl. 19 Rm. C and D—
Capacity 32)
Exhibit on Cystoscopic Equipment. (Rm. 1030, Babies
Hosp., 10th Fl.—Capacity 32)
Exhibit of Urological Pathology Department. (Rm. 510,
15th Fl., Phys & Surg Bldg.—Capacity 32)
PRESBYTERIAN NEW YORK ORTHOPEDIC
HOSPITALS

Fracture Service

Clinic. FRACTURE SERVICE STAFF (Main O.R. 19th
Fl.—Capacity 8)
30-4200. *Fractures and Traumatic Surgery* Nonopera-
tive Clinic. Shoulder Cliff Injuries and Recurrent
Shoulder Dislocations with Follow-up Results. HAR-
VEY L. McLAUGHLIN (Rm. 417 16th Fl. Phys.
& Surg. Bldg.—Capacity 100)
Results of Open and Closed Treatment of Pott's Frac-
tures. BARBARA B. STINEBAUGH (Same Rm.)

ROOSEVELT HOSPITAL

9:00-12:00. *General Surgery* Operative Clinic: Surgical
Treatment of Lesions of the Colon Subtotal Colectomy
for Ulcerative Colitis. Rounds and Demonstration of
Patients. HENRY W. CAVE and STAFF (O.R. 1 & 3
and 4—Capacity 42)
9:00-12:00. *Gynecology* Operative Clinic. Gynecology
THOMAS G. PRIGENT, ARTHUR V. GREELY and STAFF
(O.R. 2—Capacity 14)
9:00-12:00. *Radical Mastectomy* Rounds, Presenta-
tion of Cases and Illustration of Late Results WILLIAM
C. WHITE and STAFF (O.R. 1-4—Total capacity 56)
11:00-12:00. *Gynecology* Nonoperative Clinic. The Early
Results of Malignancies of the Female Pelvic Organs
Prolapse of the Uterus, etc. (Conference Room 1—
Capacity 50)
30-5200. *General Surgery* Nonoperative Clinic: Surgical
Treatment of Lesions of the Colon Sequelae, Complica-
tions and Late Results of the Surgical Treatment of
Ulcerative Colitis (Motion Pictures of Technique of
Ileostomy and Colectomy Presentation of Cases
Showing Late Results) HENRY W. CAVE. (Same Rm.)
The Late Results of Carcinoma of the Thyroid Gland.
JAMES E. THOMPSON. (Same Rm.)
Presentation of Cases Illustrating Interesting and Un-
usual Fractures (Illustrations) WILLIAM H. CASE
8:00. (Same Rm.)
Nonunion of Fractures of the Femoral Neck, Case Presen-
tations (Illustrations) M. BICKERT HOWARTH.
(Conference Rm. 2—Capacity 50)

ST LUKE'S HOSPITAL

8:30-12:00. *Genitourinary Surgery* Operative Clinic.
Urologic Survey GEORGE HOCH and STAFF (Lytle
O.R.—Capacity 15)
11:00-12:00. *Orthopedic Surgery* Clinical Demonstration
Pathological Demonstration of Internal Derangement
of Knee Joint with End Results DAVID BOWWORTH,
EDWARD WINKANT (Staff Conference Rm.—Capacity
60)
Trochanteric Fractures of Femur Treatment and End-
Results FRED THOMPSON (Same Rm.)
300-5200. *Genitourinary Surgery* Clinical Demonstra-
tions. Follow-up on War Paraplegics. BOBIS PETROFF
& flow up on Renal Tumors. JOHN TAYLOR. (Same
Rm.)

Follow-up on Vesical Neck Obstructions to Abdomino-
perineal Resection. JAMES WADDE. (Same Rm.)
Results of Transurethral Resection. GEORGE HOCH
(Presented by C. H. PLACK) (Same Rm.)
Combined Treatment of Transvesical Resection and Ra-
diotherapy of Bladder Tumors E. CRAIG COATES
(Same Rm.)
Renal Rickets. ALLEY (Same Rm.)

Carcinoma of the Lung. ADRIAN LAMBERT

BELLEVUE HOSPITAL—THIRD (NEW YORK UNIVERSITY) SURGICAL DIVISION

8:00-10:00. *Neurosurgery* Operative Clinic. Thoracolumbar Sympathectomy for Hypertension. H. M. WICKREME, JOHN H. MULLHOLLAND and STAFF (Surg. G. R. K. 5—Capacity 5)8:00-10:00. *General Surgery* Operative Clinics (Operating Rm. K. 5 & K-6, Psychiatric Surgical Operating Room). JOHN H. MULLHOLLAND and STAFF. Thyroidectomy. JOHN A. LAWLER (O. R. A.)

Anterior Resection of the Rectum for Carcinoma. SAMUEL STANFORD (O. R. B.)

Section of Splincter of Oddi for Pancreatitis. JOHN MULLHOLLAND, HENRY DOUGLASS (O. R. C.)

Lumbar Sympathectomy for Peripheral Vascular Disease. WALLACE B. MURPHY (Operating Room D)

Murray-Brackett Osteotomy for Unilateral Fracture of Neck of Femur. IRVING S. SIEG (Bone Rm. K-6—Capacity 5)

10:00-12:00. *General Surgery* Nonoperative Clinics (I & K Bldg. Stewart Amph.)

Results of Section of Splincter of Oddi for Pancreatitis. HENRY DOUGLASS

Role of Sulfadiazine in Thyrotoxic Patients. JOHN A. LAWLER

Results and Follow-up in Carcinoma of the Rectum Treated with Anterior Resection. SAMUEL STANFORD

Pulmonary Complications in Surgery. WALTER CRANDALL

Fluid Compartments in Depleted Surgical Patients and Changes During Repletion. CO. TUN.

General Principles of Reconstructive Plastic Surgery of the Face. JOHN M. CONVERSE

Program of Postgraduate Training in Surgery at New York University College of Medicine. JOHN H. MULLHOLLAND

8:30-10:00. *Gynecology* Operative Clinic. WILLIAM E. STURMFOORD and STAFF (K-6 O. R.—Capacity 5)

Total Hysterectomy for Fibroid. CLAUDE E. HYATON.

Unusual Cases of Dysmenorrhea in Young Women—A Report of 3 Cases (paper)

Fascial Transplant for Relief of Strain Incontinence in Patients with Previous Operations. WILLIAM E. STURMFOORD

Pulmonary Complications in Surgery. WALTER CRANDALL

Fluid Compartments in Depleted Surgical Patients and Changes During Repletion. CO. TUN.

General Principles of Reconstructive Plastic Surgery of the Face. JOHN M. CONVERSE

Program of Postgraduate Training in Surgery at New York University College of Medicine. JOHN M. MULLHOLLAND

10:00-12:00. *Otolaryngology* Operative Clinic (K-6 O. R.) Laryngeal Surgery. JOHN F. DALY and STAFF10:00-12:00. *Anesthesia*. Demonstrations (K-6 O. R.). The Aesthetic Nerve Block Clinic. Anesthesia and Shock. E. A. ROYCE and STAFF10:00-12:00. *Rehabilitation and Physical Medicine* for Paraplegic. Demonstration of Program for the Rehabilitation of Paraplegic Patients. GEORGE DEWEY. (Wards F. O-3, F & G Bldg.—Capacity 25)10:00-12:00. *Case Demonstrations*. In the Study Room. J. GALVET, EDGAR H. BATES, JEROME W. MARCOT, WILLIAM MACKLER. (I & K Bldg. Stewart Amph.—Capacity 50)

BETH ISRAEL HOSPITAL

9:00-12:00. *Gynecology* Operative and Nonoperative Clinics. HENRY TALK and STAFF (Main O. R. 1st Fl.—Capacity 6 and 1st Lecture Rm.—Capacity 30)10:00-12:00. *Anesthesia*. Nonoperative Clinic. Clinical Demonstrations—Film on Hemorrhage and Shock. S. G. HENRIK and STAFF (3rd Fl. Lecture Rm.—Capacity 30)

FLOWER AND FIFTH AVENUE HOSPITALS

9:00-12:00. *Neurosurgery*. Operative Clinic. Lumbar Sympathectomy—Technique of Block. S. THOMAS GLASSER, DONALD E. BRACE. (Main O. R., 1st Fl.—Capacity 1)10:00-12:00. *General Surgery* Nonoperative Clinic: Head Infections. JAMES M. WENFIELD, JOHN HENRY (Amphitheatre—Capacity 300)

Nonoperative Clinic: Diseases of Vascular System. FREDERICK W. BANCROFT (Same Rm.)

10:00-12:00. *General Surgery* Nonoperative Clinic: Exhibit of Postgraduate School—Regional Anesthesia. JOSEPH H. FORTA. (Same Rm.)3:00-5:00. *General Surgery* Nonoperative Clinic: Functional Concept of the Internal Ring—Surgical Application in the Repair of Inguinal Hernia—Operating Room or Cadaver. J. CLIFFORD HAYTER. (7th Fl. College Anatomy Lab.—Capacity 50)

HARLEM HOSPITAL

9:00-12:00. *Traumatic Surgery* Nonoperative Clinic: Trauma Symposium. Ward Rounds. L. T. WICKER (Wards 2A, 2B, 3rd Bldg. and Conference Rm., 5th Fl. Women's Pavilion)

Head and Neck Injuries. D. H. SMITH, J. GREENE, S. BERENSON (Same Rm.)

Fractures of the Extremities with Late Results. A. C. LOGAN, W. A. FREEMAN, A. PETERLIN, C. DE LORENZO. (Same Rm.)

10:00-12:00. *Obstetrics* Nonoperative Clinic: Obstetrical Symposium. Emergency, Toxicity of Anesthetics. A. C. POKORSKY, J. N. PLESCHKE. (Conference F. 500)

Women's Pavilion—Capacity

HOSPITAL FOR JOINT DISEASES

- 9:00-12:00. *Orthopedic Surgery* Operative Clinic. HARRY SPÖRSCHEIM and STAFF
Transcervical Osteotomy for Slipped Femoral Epiphysis. A. KREIER. (Surg. Amph.—Capacity 50)
Femoral Shortening for Inequality of Leg Length. B. J. MINZ. (Same Rm.)
Nonoperative Clinic: Transcervical Osteotomy. A. KREIER.
Equalization of Leg Length. B. J. MINZ.
Tendon Transplantation for Radial Nerve Paralysis. H. ALTMAN. (Lecture Rm.—Capacity 60)
2:00-3:00. *Orthopedic Surgery* Nonoperative Clinic Demonstration X Rays of Primary Bone Tumors. MAURICE POMERANCE. (Lecture Rm.—Capacity 50)
3:00-4:00. *Ophthalmology* Operative Clinic: Operations on the Eye. JAMES W. SMITH. (Small O.R.—Capacity 5)
3:00-4:00. *General Surgery* Operative Clinic Surgery of the Hand. LEO MAYER. (Surg. Amph.—Capacity 50)
3:00-4:00. *Orthopedic Surgery* Nonoperative Clinic Surgical Anatomy Mechanism of Motion of Thumb. EMANUEL KAPLAN. (Lecture Rm.—Capacity 50)

HOSPITAL FOR SPECIAL SURGERY

- 8:30-12:00. *General Surgery* Operative Clinic. Operations by General Surgical Department. F. BECKMAN and STAFF. (Main O.R.—Capacity 32)
9:00-12:00. *Orthopedic Surgery* Adult Orthopedic Problems. PHILIP D. WILSON, R. STEINBERG and STAFF. (Lecture Rm.—Capacity 100)
2:00-5:00. *Orthopedic Surgery* Nonoperative Clinic Hip Problems.
Treatment of Fractures of Femoral Neck in the Aged. FERDINAND VON SAAL. (Same Rm.)
Anterior Wedge Osteotomy for Slipped Femoral Epiphyses. LEWIS CLARK WAGNER. (Same Rm.)
Trochanteric Arthroplasty. PHILIP D. WILSON. (Same Rm.)
Transplantation of External Oblique for Paralysis of Hip Abductors. LOWELL THOMAS, T. CAMPBELL THOMPSON, L. RAMSAY STRAUSS. (Same Rm.)
Treatment of Congenital Dislocation of the Hip with Anterior. FRANCIS CARR. (Same Rm.)
Idiopathic Aseptic Necrosis of the Hip in Adults. WILLIAM COOPER. (Same Rm.)

LENOX HILL HOSPITAL

- 9:00-12:00. *General Surgery* Nonoperative Clinic Rehabilitation and Physical Medicine. GEORGE G. DEWEY. (Elmhurst Auditorium—Capacity 450)
2:00-5:00. *General Surgery* Nonoperative Clinics
The Anti Coagulants and Their Use in Surgical Practice. CARL REICH. (Elmhurst Auditorium—Capacity 450)
RH Factor and Blood Bank Demonstration. JACOB GRIGER. (Same Rm.)

LYING-IN HOSPITAL

(See New York Hospital)

MANHATTAN EYE, EAR AND THROAT HOSPITAL

- 9:00-12:00. *Ophthalmology* Operative Clinic: Cataract Extraction, Corneal Transplant, Dacryocystorhinostomy G. BOVACOLLO. (Eye O.R., 6th Fl.—Capacity 5)
10:00-12:00. *Ophthalmology* Nonoperative Clinic: Laboratory Demonstration Bacteriology of the Eye. F. C. KELL, JR. (Path. Lab. 6th Fl.—Capacity 5)

- 10:00-12:00. *Otolaryngology* Nonoperative Clinic Demonstration Results in Cases of Arytenoidectomy J. D. KELLY. (Kelly Clinic, 2nd Fl.—Capacity 24)
10:00-12:00. *Ophthalmology and Otolaryngology* Nonoperative Clinic Plastic Surgery Clinic Conference on End-Results, Lantern Slides and Motion Pictures. J. M. CONVERSE, BYRON SMITH. (Conference Rm. 2nd Fl.—Capacity 70)
1:00-4:00. *Ophthalmology and Otolaryngology* Operative Clinic Plastic Surgery. BYRON SMITH, J. M. CONVERSE. (O.R. 6th Fl.—Capacity 5)
2:00-4:00. *Ophthalmology* Operative Clinic Corneal Graft R. T. PATON. (Same Rm.)
2:00-4:00. *Ophthalmology* Nonoperative Clinic Demonstration Vitreous Substitution Technique and End Results. MILO FETZ. (Eye Bank Lab. 10th Fl.—Capacity 12)
2:00-4:00. *Ophthalmology and Otolaryngology* Nonoperative Clinic Radiology Clinic: Radiation Therapy in Ophthalmology Results of Radiation in Laryngeal Tumors. MAURICE LENT, J. R. FREED, C. OKRAINEZ. (Radiotherapy Dept., 3rd Fl.—Capacity 12)
2:00-4:00. *Otolaryngology* Nonoperative Clinic Demonstration Radiation of Hypertrophied Lymphoid Tissue of Nasopharynx. H. D. TATNER. (Kelly Clinic, 2nd Fl.—Capacity 24)
2:00-5:00. *Otolaryngology* Operative Clinic Arytenoidectomy Operation. J. D. KELLY. (O.R. 6th Fl.)
3:00-5:00. *Ophthalmology* Nonoperative Clinic Demonstration Postoperative Corneal Graft Cases. R. T. PATON. (Conference Rm. 2nd Fl.—Capacity 70)

MEMORIAL HOSPITAL

- 9:00-12:00. *Tumor Surgery* Nonoperative Clinic Discussion Five Year Survivals in Lymphomas and Leukemias. LLOYD F. CRAVER. (Auditorium—Capacity 350)
The Use of Newer Nitrogen Mustard Compounds in the Treatment of Lymphomas and Leukemias. JOSEPH BURCHERL. (Same Rm.)
Nitrogen Mustard As a Palliative Agent in Cancer. DAVID KARSHOFKY. (Same Rm.)
The Role of Radioactive Iodine in Thyroid Cancer. JACK THURVELL. (Same Rm.)
Reasons for Delay in the Diagnosis of Cancer. JOHN L. LEACH, GUY ROBBINS. (Same Rm.)
Preoperative and Postoperative Care for Cancer of the Lung. JOHN E. LEACH, HENRY DIAMOND. (Same Rm.)
Study of Diagnostic Methods and Treatment of Cancer of the Lung. JOHN S. LADUE. (Same Rm.)
The Internist's Role in Cancer. WILLIAM H. LEWIS, JR. (Same Rm.)
Treatment of Shock. HENRY TAYLOR. (Same Rm.)
2:00-5:00. *Tumor Surgery* Nonoperative Clinic: Follow up Results in Different Types of Breast Cancer. FRANK ADLER. (Same Rm.)
3:30-5:00. *Tumor Surgery* Follow up Results in Patients with Metastatic Carcinoma of the Breast with Endocrine Therapy. FRANK ADLER. (Same Rm.)

METROPOLITAN HOSPITAL

- 9:00-12:00. *General Surgery* Nonoperative Clinic: Preoperative and Postoperative Treatment. JAMES M. WIDFIELD and STAFF and LOUIS R. KATZMAN, JOHN HERKELIN, EDWARD J. MCCABE. (Conference Rm.—Capacity 60)
General Discussion.
Fluid Balance. JOHN HERKELIN. (Same Rm.)

Early Ambulation and Early Exercise. EDWARD J. McCABE. (Same Rm.)

200-400. *Obstetrics and Gynecology* Nonoperative Clinics Interesting Ovarian Tumors. W. B. SILVERBLATT (Same Rm.)

Ectopic Pregnancy with Especial Reference to Posterior Colotomy. JOHN E. TATCHEL. (Same Rm.)

100-400. *Orthopedic Surgery and Fractures*. Nonoperative Clinic; Demonstration of End Results of Injuries to Lower Extremities. MERRICK J. WILSON and STAFF (Conference Rm., Welfare Dispensary, 80th E. and East End Ave.—Capacity 30)

MONTEFIORE HOSPITAL

100-300. *Therapeutic Surgery* Operative and Nonoperative Clinic. ARTHUR H. AYERS, LEONOR KROES. (O.R.—Capacity 1)

MOUNT SINAI HOSPITAL

8 30-1200. *General Surgery* Operative Clinic. Subtotal Gastrectomy and Infraesophageal Vagotomy for Duodenal Ulcer with Stenosis. RALPH COLE (Surg. Amph.—Capacity 100)

Nonoperative Clinics: Presentations Physiologic Differences between Gastric and Duodenal Ulcers. FRANK HOLLANDER. (Same Rm.)

A Rational Approach to the Surgery of Juxta Esophageal Ulcer. LEONARD DUCKERMAN. (Same Rm.)

Problems in the Treatment of Gastrojejunocolic Fistula. FRANK KILGORESTEIN. (Same Rm.)

Follow-up Results in Subtotal Gastrectomy for Gastric and Duodenal Ulcer. STANFORD MACR. (Same Rm.)

Indications for Vagotomy: Peptic Ulcer. RALPH COLE (Same Rm.)

100-300. *Otorhinolaryngology* Operative and Nonoperative Clinic: Inflammatory and Neoplastic Diseases of the Focal Sinuses. RUDOLPH KRAMER, MORRIS BECKER, IRVING GOLDMAN, JOSEPH DRUSE, SAMUEL ROSEN and STAFF. (Same Rm.)

Carcinoma of the Larynx and Results, Treatment by Radiation Therapy. RUDOLPH KRAMER, MORRIS BECKER, IRVING GOLDMAN, JOSEPH DRUSE, SAMUEL ROSEN and STAFF. (Same Rm.)

NEW YORK EYE AND EAR INFIRMARY

100-200. *Otolaryngology and Ophthalmology* Fundamentals of X-ray Diagnosis in Ophthalmology and Otolaryngology. IRVING SCHWARTZ (X-ray Viewing Rm.—Capacity 0)

100-300. *Ophthalmology and Otorhinolaryngology* Discussion. Allergy in Eye, Ear, Nose and Throat. HOWARD WESTCOTT (Allergy Clinic—Capacity 30)

100-400. *Otorhinolaryngology* Demonstration Equipment Including the Biplanar Fluoroscope in the Bronchoscopic Clinic. MAXWELL D. RYAN. (Bronchoscopic Clinic—Capacity 30)

1 30-430. *Otorhinolaryngology* Demonstration Methods—Allergy. J. H. BARNARD. (Allergy Clinic—Capacity 30)

100-300. *Ophthalmology* Demonstration Postoperative Treatment. R. MEKE and W. JOHNSON and ASSOCIATES. (Clinic Rm.—Capacity 30)

Diagnostic Studies with Special Reference to Muscle Studies. T. BOYCE and ASSOCIATES. (Same Rm.)

Surgery with Special Reference to Lacrimal Apparatus. B. PAYNE and R. McCLAMAHAN and ASSOCIATES. (Eye O.R.—Capacity 1)

Routine Clinics of the New York Eye and Ear Infirmary will be held as usual during this period, all Fellows of the American College of Surgeons are cordially invited to attend.

NEW YORK HOSPITAL

900-1200. *Plastic and Reconstructive Surgery*. Operative and Nonoperative Clinics: One Stage Push Back Operation for Congenitally Short Palate. Miscellaneous Case Presentations. HERBERT CONWAY. (Rm. F630—Capacity 70)

Speech Therapy in Cases of Cleft Palate. E. FITZ. (Same Rm.)

End-Results Following Radical Breast Amputation With Split Skin Grafting. CHARLES NEWMAN. (Same Rm.)

Demonstration of Technique of Tattooing Skin Grafts and Port Wine Stains. HERBERT CONWAY, FRANK ELISON. (Same Rm.)

900-1200. *Ophthalmology* Operative Clinic: Intracapsular Cataract; Glaucoma, Strabismus. JOHN McALL and STAFF. (7th Fl. O.R. 1 Rm.—Capacity 30)

1200-500. *General Surgery* Operative and Nonoperative Clinic. FRANK GLENN and STAFF. Surgical Treatment of Acute Cholecystitis. FRANK GLENN. (College Auditorium, Rm. 8001—Capacity 350)

Pathology of Acute Cholecystitis. N. C. FOOTE. Complications of Acute Cholecystitis. S. R. MOORE.

Diverticulitis of Large Bowel, Follow-up Studies. GUNTER CHILDS.

Follow-up Studies of Polyps of the Large Intestine. S. W. MOORE.

Demonstration and Exhibit. Surgical Pathological Laboratory. N. C. FOOTE.

1200-500. *General Surgery* Demonstration. Surgical Anatomy. Anatomy Involved in Lumbar and Thoracolumbar Sympathectomy. EMMETT LAMPE. (Rm. A 38—Capacity 5)

1200-500. *Otorhinolaryngology* Nonoperative Clinic: One Presentations and Postoperative Results. Laryngofissure, Carcinoma of Antrum, Meningioma with Petrositis and Meningitis. Acute Frontal Sinusitis with Meningitis. ARTHUR PALMER and ASSOCIATES. (Rm. F630—Capacity 70).

NEW YORK HOSPITAL

LYING-IN HOSPITAL

900-1200. *Gynecology* Operative Clinic: Gynecological Operations. H. J. STANLEY. (Gyn. O. R., 2 Rm.—Capacity 30)

1200-500. *Obstetrics and Gynecology* Nonoperative Clinic: Late Results in Patients with Recurrent Abortion. CARL T. J. VERT. (Lecture Rm.—Capacity 100).

Echampsia. H. J. STANLEY. (Same Rm.)

Treatment of Endocervicitis. RALPH W. G. CUL. (Same Rm.)

X-ray Pelvimetry. CHARLES M. McLAKE. (Same Rm.)

Miscellaneous Abortion. FRANK SMITH. (Same Rm.)

NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL

900-1200. *Orthopedic Surgery* Rounds. End-Result Conference. ALAN DE FOREST SMITH. (7th Fl. Assembly Rm.—Capacity 30)

Osteoarthritis of the Hip. FRANK STURGEONFIELD. (Same Rm.)

Slipping of the Upper Femoral Epiphysis. M. H. HOWARTH. (Same Rm.)

30-400. *Orthopedic Surgery*. General Orthopedic Clinic. LEONIDAS A. LASTROUKIS and STAFF. (Same Rm.)

Scold's Clinic. WILLIAM H. VON LACKEN. (Same Rm.)

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS

411

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL

- 8:30-9:30. *Neurosurgery* Operative Clinic. Diagnostic Procedures. J. A. MACLEAM (O.R. 4—Capacity 10)
 8:30-11:30. *Urology* Operative Clinic. CLARENCE BARNES (O.R. 5—Capacity 10)
 8:30-12:00. *Tumor Surgery* Operative Clinic. H. W. MEYER (O.R. 3—Capacity 10)
 8:30-12:00. *General Surgery* Operative Clinic. E. J. DICKSON (O.R. 1—Capacity 10)
 Operative Clinic. R. FRANKLIN CARTER. (Surg. Amph. 1—Capacity 50)
 10:30-12:30. *General Surgery* Nonoperative Clinic. Case Presentations of Operative Procedures In Gastrointestinal and Gastro-intestinal Ulcer with a Discussion of the Indications and Contra-indications for 1. S. ARTHUR LOCALLO. PHILIP A. ZOLLER. (Erdmann Auditorium—Capacity 125)
 10:30-12:30. *Traumatic Surgery* Nonoperative Clinic. Fractures. H. H. RITTER. (Amph. D—Capacity 30)
 11:30-12:00. *Oral Surgery* Operative Clinic. F. S. DUNN (O.R. 5—Capacity 10)
 12:00-1:30. *Orthopedic Surgery* Nonoperative Clinic. Demonstration of Orthopedic Conditions—Pro and Post Operative. GEORGE ANTONIO. (Amph. C)
 1:00-1:30. *Neurosurgery* Operative Clinic. J. A. MACLEAM (O.R. 5—Capacity 10)
 1:00-2:00. *Traumatic Surgery* Operative Clinic. H. H. RITTER. (Surg. Amph.—Capacity 50)

PRESBYTERIAN HOSPITAL

- 8:00-12:00. *General Surgery* Operative Clinic. Surgery of the Pancreas. JOHN S. LOCKWOOD, WILLIAM B. FARLEY. (19th Fl., Main O.R. C—Capacity each 10)
 Surgery of the Spleen. LOUIS M. ROUSSELOT, ROBERT H. ELLIOTT. (Same Rm.)
 Resection of Mandible For Carcinoma. MAURICE J. HICKY. (Same Rm.)
 Lobectomy for Chronic Bronchiectasis. RICHMOND L. MOORE. (Same Rm.)
 2:00-4:00. *General Surgery* Nonoperative Clinic. Tissue Culture as an Adjunct to Surgery. MARGARET ALLEN. (McCosh Amph. 18th Fl.—Capacity 145)
 Phlebograms of the Lower Extremity. DAVID C. BULL. (Same Rm.)
 Oxidized Cellulose in Surgery. VIRGINIA K. FRAMPTON. (Same Rm.)
 Electrophoretic Studies of Plasma in Extensive Burns. JOHN SCUDDER. (Same Rm.)
 Indications for Portacaval Shunt. ARTHUR H. BLAZER-MORE. (Same Rm.)

PRESBYTERIAN HOSPITAL

- 9:00-12:00. *General Surgery* Operative Clinic. General Clinic and Ward Rounds. Members of Staff. (O.R. 1 & 2, 6th Fl.—Capacity each 6)
 12:00-4:00. *General Surgery* Nonoperative Clinic. Congenital Diaphragmatic Hernia. Follow-up. EDWARD J. DOVOVAK. (Amph. 4th Fl.—Capacity 75)
 An Analysis of the Neoplasms in Childhood Encountered at Babies Hospital in the Past Ten Years. DOROTHY H. ANDERSEN.
 Meconium Ileus. Presentation of Cases. Motion Pictures Illustrating Pathology and Operative Procedure. ROBERT B. BLATT
 Acute Appendicitis in Children. A Comparison of the Last Two Five-Year Periods with and without Chemotherapy. EARL C. TAYLOR.

PRESBYTERIAN HOSPITAL SLOANE HOSPITAL FOR WOMEN

- 9:00-10:30. *Obstetrics and Gynecology* Operative Clinic. Total Hysterectomy. E. COLER (O.R. 17th Fl.—Capacity 30)
 10:30-12:30. *Obstetrics and Gynecology* Operative Clinic. Myomectomy. JAMES CORBACEN (Same Rm.)
 12:00-1:00. *Obstetrics and Gynecology* Nonoperative Clinic. Rh Factor in Obstetrics. J. GREER. (Lecture Rm. 17th Fl.—Capacity 40)
 1:00-2:00. *Obstetrics and Gynecology* Nonoperative Clinic. Review of Cardiac Deaths During Pregnancy 1925-47. A. J. TILMAN (Same Rm.)

PRESBYTERIAN NEW YORK ORTHOPEDIC HOSPITALS

- 9:00-12:00. *Fracture Service* Fracture Service Clinic. Fracture and Traumatic Surgery. Operative Clinic. FRACTURE SERVICE STAFF (Main O.R., 19th Fl.—Capacity 8)
 1:30-4:00. *Fractures and Traumatic Surgery* Nonoperative Clinic. Complicated Elbow Fractures with Follow-up Results. FREDERICK M. SMITH. (Rm. 417 16th Fl. Phys. & Surg. Bldg.—Capacity 100)
 Replacement of Articular Elements. STEPHEN S. HUNTER. (Same Rm.)

ROOSEVELT HOSPITAL

- 12:00-5:00. *Genitourinary* Operative Clinic. Suprapubic Prostatectomy. SIMON A. BEISLER and STAFF (O.R. 1-4—Capacity 50)
 Nonoperative Clinic. The Presentation of Patients, Illustrating the Results of Urological Procedures. Total Cystectomy With Skin and Sigmoidal Implantation. SIMON A. BEISLER and STAFF (Conf. Rm. 1—Capacity 50)
 The Replantation of Skin Ureterostomies Into the Bowel. SIMON A. BEISLER and STAFF (Same Rm.)

ST LUKE'S HOSPITAL

- 8:30-11:00. *General Surgery* Operative Clinic. General Surgery. WILLIAM MACFEE and STAFF (Lyle O.R.—Capacity 30)
 11:00-12:00. *General Surgery* Clinical Demonstrations. Benign Intrathoracic Tumors. ALEXANDER ADA. (Staff Conference Rm.—Capacity 60)
 Cervical Disks. HERBERT FARROW. (Same Rm.)
 Carcinoma of the Lower Sigmoid and Upper Rectum. WILLIAM MACFEE. (Same Rm.)
 Trends in Cure—Technique Anesthesia. EDWARD BURFORD and STAFF (Same Rm.)
 Carcinoma of Colon—Ten Year Study. EDWARD DORFMAN. (Same Rm.)
 Management of Hemorrhage for Gastric and Duodenal Ulcers. ROBERT FRANKER. (Same Rm.)
 1:00-2:00. *Ophthalmology* Operative Clinic. GUINNESS FREY and STAFF (Lyle O.R.—Capacity 6)
 2:00-3:00. *Ophthalmology* Clinical Demonstrations. Glaucoma. Results of Operation. GUINNESS FREY (Staff Conference Rm.—Capacity 60)
 Extraocular Muscle Surgery. Follow-up Results. HENRY SMITH. (Same Rm.)

ST VINCENT'S HOSPITAL

- 9:00-12:00. *Gynecology and Obstetrics* Operative Clinic. Vaginal Plastic. Abdominal Hysterectomy. Vaginal Hysterectomy. Cesarean Section. JOHN McGRATH. JAMES P. HEDDERLEY. THOMAS E. LAVELL. JOSEPH J. CORRY. THOMAS IYIDKO. ROBERT LOWRIE. JOHN

- KILGUS, WALTER P. GAGE. (O.R. C & D—Capacity each)
- 1000-1200. *General Surgery* Nonoperative Clinic: Round Table Conference: Use of Transverse Incisions. JOHN A. LAWLER. (Nurse's Lecture Rm.—Capacity 60)
- Malignant Tumors Small Intestine. CLARENCE F. HOWLEY. (Same Rm.)
- 1000-1200. *Radiology* Nonoperative Clinic: Roentgen Diagnosis of Lesions of Small Intestines. Differential Diagnosis of Mechanical and Adynamic Ileus. WALLACE MATHER and ASSOCIATES. (Viewing Rm.—Capacity 25).
- 1200-1300. *Gynecology and Obstetrics* Nonoperative Clinic: Round Table Conference.
- Study of Vaginal Spread for Carcinoma of Cervix. Differential Diagnosis in Cases of Acute Pelvic Pathology. Indications for Cesarean Section. Choice of Operation in Uterine Prolapse. JOHN McGRATH and ASSOCIATES. (Nurse's Auditorium—Capacity 50)
- 300-400. *Pathology* Nonoperative Clinic: Study of Abdominal and Chest Fluids: Evidence of Malignancy. Display of First Pathological Material. Display and Demonstration of System Diseases by Kodachrome Slides. A. ROTTINO and ASSOCIATES. (Same Rm.)
- 400-500. *General Surgery* Nonoperative Clinic: Thrombosis and Embolism. LOUIS F. SANMAR. (Same Rm.)

SLOANE HOSPITAL FOR WOMEN

(See Presbyterian Hospital)

U. S. MARINE HOSPITAL (STATEN ISLAND)

- 900-1000. *Orthopedic Surgery* Nonoperative Clinic: Orthopedic Conference. A. A. MITCHELL and STAFF. (Doctor's Staff Rm.—Capacity 75)
- 1000-1100. *General Surgery* Nonoperative Clinics: H. L. SKIDDER, CHARLES FERGUSON and STAFF.
- Regional Ileitis—Discussion and Case Presentation. (Doctor's Staff Rm.—Capacity 75)
- Benign Lesion of Colon—Discussion and Case Presentation. (Same Rm.)
- Malignant Lesion of Colon—Discussion and Case Presentation. (Same Rm.)
- 1230-1300. Luncheon at the Hospital.
- 1200-1300. *General Surgery* Operative Clinic: Stomach Resection Under Balanced Anesthesia. W. F. NICKEL and RESIDENT STAFF. (General O.R.—Capacity)
- 100-1200. *Orthopedic Surgery* Operative Clinic: Herniated Intervertebral Disc with Exploration and Fusion. H. L. SKIDDER, A. A. MITCHELL and STAFF. (General O.R.—Capacity)

VETERANS ADMINISTRATION HOSPITAL

- 900-1200. *General Surgery* Operative Clinic. EDWIN STUP. DAVID K. POKES. (Bldg. D. Rm., 5th Fl.—Capacity 20)

- 900-1200. *Neurosurgery* Operative Clinic: Frontal Lobotomy. JOHN E. SCARRY. EDWIN KATZNER. (Bldg. D. 5th Fl. Rm.—Capacity 1)
- 900-1200. *Genitourinary Surgery* Operative Clinic: LOUIS SPYVACE, EDWIN J. DREW. (Bldg. D, 5th Fl., Rm.—Capacity)
- 900-1200. *Plastic Surgery* Operative Clinic. HENRY CONWAY, CORNELIUS J. KRAMER. (Bldg. B, 5th Fl., 1 Rm.—Capacity 6)
- 900-1200. *Orthopedic Surgery* Nonoperative Clinic: Conference: Presentation of End-Results—Bone Tumors, Bone and Joint Tuberculosis. Presentation of Cases. PHILIP D. WILSON, SYDNEY N. EICHENBOM, ROBERT PATTERSON, FRANK E. STODOLSKY, and RESIDENT STAFF. (Bldg. C, 4th Fl.—Capacity 30)
- 930-1000. *General Surgery* Nonoperative Clinic: Medical Rehabilitation Clinic. HARRY KEMLER, KEN HARPODER, IRWIN D. STEIN, BERNARD STOLL, JAMES BYER. (Bldgs. B, C, & F Ground Fl.—Capacity 10)
- 100-1200. *General Surgery* Nonoperative Clinic: Result of Vagus Resection. P. K. SAUER, JOHN ECKEL, CHRISTIAN HOLMAN, FRANK J. MCGOWAN, CHARLES PRITCHARD, and RESIDENT STAFF
- 1100-1230. *Neurosurgery* Nonoperative Clinic: Frontal Lobotomy. JOHN E. SCARRY. THOMAS RYMER, HILAND L. FLOWERS.
- 130-1330. *Neurosurgery* Nonoperative Clinic: Conference: Complications in Frontal Cranioplasty Involving Frontal Sinus. Surgery of the Sympathetic Nervous System for Painful Conditions. Leptomenigeal and Porencephalic Cyst with Increased Intracranial Pressure. Surgical Treatment of Pilonidal Tract by Cervical Midline Inc. Lucic Pachymeningitis with Increased Intracranial Pressure. JOHN E. SCARRY, FRANK CHAMBER, E. G. KATZNER, J. LAWRENCE POOL. (Bldg. A, 3rd Fl.—Capacity 200)
- 100-1200. *Otolaryngology* Operative Clinic. PETER D. LATTELLA. (Bldg. B 5th Fl.—Capacity 1)
- 330-500. *Urology* Nonoperative Clinic: Conference: ARTHUR DRAH, LOUIS SPYVACE, PERLIN SYDNER, EDWIN J. DREW, WILLET WHITMORE, JOHN K. LATTELL, and RESIDENT STAFF. (Bldg. A, 3rd Fl.—Capacity 200)

EXHIBITS

(Bldg. A, 3rd Fl.)

Anesthesia Section	Results of Vagus Resection
Bronchogenic Carcinoma	Pathology Section
Review of 600 Cases	Medical Illustrations
Intracranial Neoplasms	Laboratory
Residency Training Program	Plastic Surgery
Organization of Surgical Division	Prosthetic Appliances

CLINICS IN BROOKLYN—LONG ISLAND HOSPITALS

Thursday

BROOKLYN EYE AND EAR HOSPITAL

- 900-1200. *Ophthalmology Otolaryngology and Faciomaxillary Surgery* Late Results in Faciomaxillary Surgery. Late Results in Laryngotomies. Late Results in Glaucoma Surgery. Angiostomometry Exhibit. Motion Picture Demonstration on the Development of the Human Eye as Shown by Animation. G. R. O'BRIEN, JOHN P. BAKER, CHARLES LAMBERTA, JOHN EVANS, G. H. PATT. (Ph.D.). (Solarium—Capacity 40).

- 100-1200. *Plastic Surgery* Operative Clinic: AARL GERALD R. O'BRIEN and STAFF. (5th Fl. O.R. 1-4 Capacity 20)

CUMBERLAND HOSPITAL

- 900-1200. *Fractures and Traumatic Surgery* Operative and/or Nonoperative Clinics: Pinning for Femur Neck Fracture. LEO FARRER and STAFF. (Auditorium—Capacity 300).

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS

413

KINGS COUNTY HOSPITAL

Late Results in Fracture of Femur Neck. (Same Rm.)
 Traumatic Abdomen JOSEPH I. AXTON (Same Rm.)
 Ward Rounds with X-ray Studies of Various Types of Fractures. LEO FALKER and STAFF (Wards 46, 51—Capacity 15)
 12:30-1:30. Luncheon at the Hospital.
 1:30-3:00. Fractures and Traumatic Surgery Nonoperative Clinics
 Discussion. NOUNKON, Late Results and General—Capacity 300
 Ward Rounds with Demonstration of Apparatus in Use. JOSEPH NEVINS and STAFF (Auditorium)
 JOSEPH NEVINS and STAFF (Wards 46, 51—Capacity 15)
 Gadgets and Their Use in Fracture Treatment JOSEPH NEVINS and STAFF (Same Rm.)
 Head Injuries. Late Results. FRANK TURNEY (Auditorium—Capacity 300)

8:30-12:00. *General Surgery* Operative Clinics
 Dorsal Cordotomy for Painful Phantom Foot. E. JEFFERSON BROWDER. (B. Bldg. O.R. 1-10—Capacity 15)
 Sympathectomy for Arterial Hypertension. EVERETT CORRADINI (Same Rm.)
 Capsular Fiber Section for Parkinsonism. E. JEFFERSON BROWDER. (Same Rm.)
 Dorsal Rhizotomy for Spasticity of Cerebral Palsy FRANK TURNEY (Same Rm.)
 9:00-12:00. *General Surgery* Operative Clinic. JOSEPH TENOPPE and STAFF (B. Bldg. O.R. 1-10—Capacity 15)
 9:00-12:00. *Thoracic Surgery* Operative Clinic. Segmental Resection of the Lung. LEW A. HOCHBERG. (B. Bldg. O.R.F. Capacity 15)
 12:00-3:00. *General Surgery* Nonoperative Clinic Follow-up Fractures JOSEPH TENOPPE. (Main Bldg. Rm. B3—Capacity 50)
 3:00-5:00. *Vascular Surgery* Nonoperative Clinics
 The Cerebral Hemangioblastomas EVERETT CORRADINI (Main Bldg. Lecture Rm. 1st Fl.—Capacity 40)
 Cysticercus Disease of the Brain. LESTER KIERD (Same Rm.)
 Surgery for Parkinson's Disease. E. JEFFERSON BROWDER. (Same Rm.)
 Management of Fractures of the Spine with Spinal Cord Damage. FRANK TURNEY (Same Rm.)
 Subdural Hematoma. RICHARD GRIMES. (Same Rm.)
 3:00-5:00. *Thoracic Surgery* Nonoperative Clinics
 Lung Abscess as Seen at the Kings County Hospital ALFRED D. BICUTMAN. (F. Bldg. Chapel—Capacity 100)
 Pneumomycosis in Cases of Pulmonary Tuberculosis. EDWIN H. GRIFFIN. (Same Rm.)
 Some Experiences in the Management of Chronic Empyema. ELIOT K. JOHNSON. (Same Rm.)
 Paradoxical Respiration—Its Causes, Consequences and Treatment. LEW A. HOCHBERG. (Same Rm.)

HOUSE OF ST GILES THE CRIPPLE

11:00-12:00. *Orthopaedic Surgery* Operative Clinic. Abduction Traction Splint for Congenital Dislocation of Hip. C. C. VITALS (Roof Clinic—Capacity 60)
 Shoulder Fusion, for Polio Field Shoulders, five-year Follow-up. Demonstration of Cases. C. C. VITALS. (Same Rm.)
 Follow-up on Shelf Operation, for Congenital Dislocation of Hip. Presentation of Cases. J. GLANZENTH. (Same Rm.)
 Recurrent Clubfoot, Demonstration of Cases Following Resection of Head of Talus Plus Transplantation of Anterior Tibial Tendon. A. OAKES. (Same Rm.)
 Demonstration of Cases Following Tereb Major Transplantation for Obstetrical Palsy C. C. VITALS. (Same Rm.)

JEWISH HOSPITAL

8:00-10:00. *General Surgery* Operative Clinic. PAUL W. ASCHEVER and STAFF (Amph. 1—Capacity 25)
 Operative Clinic. LEO S. SCHWARTZ and STAFF (Amph. 2—Capacity 25)
 10:00-12:00. *Gynecology and Obstetrics* Nonoperative Clinic
 Puerperal Hematomas of Vulva. PAUL PEDOWITZ (Auditorium—Capacity 300)
 Subcutaneous Heparin in Thromboembolic Disease in Gynecology and Obstetrics HARRY J. GREENGLASS. (Same Rm.)
 A Study of Pelvic Drive in Obstetrics EDWIN AL. GOLD. (Same Rm.)
 Hydranidias and Infertility CHARLES BIENBERG. (Same Rm.)
 Failed Forcyp. LEONORE DACHMAN WILLIAM PUM. (Same Rm.)
 Studies with Gonadotropin. SAMUEL A. WOLFE, IRWIN NEVINS. (Same Rm.)
 12:00-1:00. *Gynecology and Obstetrics* Nonoperative Clinic
 Diagnosis and Treatment of Solitary Cyst of the Kidney by Aspiration and Infection. ABRAHAM D. SEGAL. (Conference Rm.—Capacity 40)
 Treatment of Hydrocoele by Sclerosing Agents. LOUIS H. BARKETZ. (Same Rm.)
 Peritonitis and Oviditis Puer Complicating Urologic Procedures ZACHARY R. COTTLER, SAMUEL PARMAR. (Same Rm.)
 Destructive Urography in Children. PERRY KATZEM. (Same Rm.)
 Serum Acid Phosphatase in the Diagnosis and Management of Carcinoma of the Prostate. LEONORE KIM MCEL, PAUL W. ASCHEVER. (Same Rm.)

KINGS COUNTY HOSPITAL LONG ISLAND COLLEGE DIVISION

8:30-12:00. *General Surgery* Operative Clinics
 Gastric Resection. EDWARD P. DUNN. (B. Bldg. O.R. 1-10—Capacity 30)
 Large Bowel Resection CHARLES B. JONES. (Same Rm.)
 Gall Bladder and Common Duct Exploration. PHILIP E. LEAR. (Same Rm.)
 Ligation Patent Ductus Arteriosus. JOHN L. MADDEN. (Same Rm.)
 12:45-3:00. *General Surgery* Nonoperative Clinics
 Diagnosis and Treatment of Lymphogranuloma Venereum, Anus Rectum, and Colon. CHARLES B. JONES. (Same Rm.)
 Paraduodenal Hernia, Report of Four Cases. PHILIP E. LEAR. (Same Rm.)
 Cosmetic Incision for Excision of Benign Breast Tumors and for Suppurative Diseases of the Female Breast. GASTALDO T. DEYANNA. (Same Rm.)
 Tetanus—A Surgical Problem. Experience with Five Hundred Cases in China. PHILLIPS F. GREENE. (Same Rm.)
 Gastrojejunocolic Fistula. Six Case Reports JOHN L. MADDEN. (Same Rm.)
 Follow-up Results in Hip Nailing Operations in Femoral Neck. ARNOLD F. SAMUELS. (Same Rm.)

- KELGUS, WALTER P. GAGE. (O.R. C & D—Capacity each 50).
- 100-100. *General Surgery* Nonoperative Clinic Round Table Conference Use of Transverse Incisions. JOHN A. LAWLER. (Nurse's Lecture Rm.—Capacity 60)
- Malignant Tumors Small Intestine. CLARENCE P. HOWLEY (Same Rm.)
- 1000-1200. *Radiology* Nonoperative Clinic Roentgen Diagnosis of Lesions of Small Intestines. Differential Diagnosis of Mechanical and Adynamic Ileus. WALLACE MAYER and ASSOCIATES. (Viewing Rm.—Capacity 25)
- 1200-1300. *Gynecology and Obstetrics* Nonoperative Clinic Round Table Conference
- Study of Vaginal Spread for Carcinoma of Cervix Differential Diagnosis in Cases of Acute Pelvic Pathology Indications for Cesarean Section. Choice of Operation in Uterine Prolapse. JOHN McGRATH and ASSOCIATES. (Nurse's Auditorium—Capacity 50)
- 1300-1400. *Pathology* Nonoperative Clinic Study of Abdominal and Chest Fluids for Evidence of Malignancy Display of First Pathological Material. Display and Demonstration of System Diseases by Kodachrome Slides. A. ROTTINO and ASSOCIATES. (Same Rm.)
- 1400-1500. *General Surgery* Nonoperative Clinic Thrombosis and Embolism. LOUIS F. BARNER. (Same Rm.)

SLOANE HOSPITAL FOR WOMEN (See Presbyterian Hospital)

U. S. MARINE HOSPITAL (STATEN ISLAND)

- 9:00-1:00. *Orthopedic Surgery* Nonoperative Clinic: Orthopedic Conference. A. A. MICHELS and STAFF (Doctor's Staff Rm.—Capacity 75)
- 100-130. *General Surgery* Nonoperative Clinics H. L. SCHWARTZ, CHARLES FERGUSON and STAFF
- Regional Ileitis—Discussion and Case Presentation (Doctor's Staff Rm.—Capacity 75)
- Benign Lesion of Colon—Discussion and Case Presentation. (Same Rm.)
- Malignant Lesion of Colon—Discussion and Case Presentation. (Same Rm.)
- 130-100. Luncheon at the Hospital.
- 200-300. *General Surgery* Operative Clinic. Stomach Resection Under Balanced Anesthesia. W. F. NICHOL and RESIDENT STAFF (General O.R.—Capacity 100)
- 300-300. *Orthopedic Surgery* Operative Clinic Herniated Intervertebral Disc with Exploration and Fusion. H. L. SCHWARTZ, A. A. MICHELS and STAFF (General O.R.—Capacity 100)

VETERANS ADMINISTRATION HOSPITAL

- 9:00-12:00. *General Surgery* Operative Clinic. EDWIN SELZ DAVID K. PETER. (Bldg. D Room 2th Fl.—Capacity 20)

- 9:00-12:00. *Neurosurgery* Operative Clinic: Frontal Lobotomy. JOHN E. SCARFF, ERIC KREIDER. (Bldg. D 2th Fl. 1 Rm.—Capacity 10)
- 9:00-100. *Genitourinary Surgery* Operative Clinic: LOTS SPITVACK, EDWIN J. DREW. (Bldg. D 2th Fl. Rm.—Capacity 10)
- 9:00-12:00. *Plastic Surgery* Operative Clinic. HENRY CONWAY CORNELIUS J. KRAHSEL. (Bldg. B 5th Fl. Rm.—Capacity 10)
- 9:00-100. *Orthopedic Surgery* Nonoperative Clinic Conference: Presentation of End-Results—Bone Tumors, Bone and Joint Tuberculosis. Presentation of Cases. PHILIP D. WILSON, SYDNEY N. ECKHARDT, ROBERT PATTERSON, FRANK E. STEINBUEHL, and RESIDENT STAFF (Bldg. C, 4th Fl.—Capacity 10)
- 9:30-100. *General Surgery* Nonoperative Clinic: Medical Rehabilitation Clinic. HARRY KESLER, KURT HARPOUDER, IRWIN D. STEIN, BERND STOLL, JACOB BYER. (Bldgs. B, C, & F Ground Fl.—Capacity 20)
- 1200-130. *General Surgery* Nonoperative Clinic: Result of Vagus Resection. P. K. SALTER, JOHN ECKHARDT, CHARLTON HOLMAN, FRANK J. MCGOWAN, CHARLES PRUITT, and RESIDENT STAFF
- 100-12:30. *Neurosurgery* Nonoperative Clinic: Frontal Lobotomy. JOHN E. SCARFF, THOMAS RYAN, HILAND L. FLOWERS.
- 10-130. *Neurosurgery* Nonoperative Clinic: Conference: Complications in Frontal Cranioplasties Involving Frontal Sinus. Surgery of the Sympathetic Nervous System for Painful Conditions. Leptomenigeal and Porencephalic Cyst with Increased Intracranial Pressure. Surgical Treatment of Pilonidal Limb. Compression of the Anterior Pyramidal Tract by Cervical Midline Disc. Lentic Pachymeningitis with Increased Intracranial Pressure. JOHN E. SCARFF, FRANK CHAMBER, E. G. KREIDER, J. LAWRENCE POOL. (Bldg. A, 3rd Fl.—Capacity 200)
- 1000-1400. *Otolaryngology* Operative Clinic. PETER D. LATTELLA. (Bldg. B 5th Fl.—Capacity 10)
- 130-1200. *Urology* Nonoperative Clinic: Conference. ARTHUR DEAN, LOUIS SPITVACK, PETER SYDNEY, EDWIN J. DREW (WILLET WESTGATE, JOHN K. LATTELL, and RESIDENT STAFF (Bldg. A, 3rd Fl.—Capacity 200)

EXHIBITS (Bldg. A, 3rd Fl.)

- | | |

CLINICS IN BROOKLYN—LONG ISLAND HOSPITALS

Thursday

BROOKLYN EYE AND EAR HOSPITAL

- 9:00-12:00. *Ophthalmology Otolaryngology and Faciomaxillary Surgery* Late Results in Faciomaxillary Surgery Late Results in Laryngotomies. Late Results in Glaucoma Surgery Angiostomometry Exhibit. Motion Picture Demonstration on the Development of the Human Eye as Shown by Animation. G. R. O'BRIEN, JOHN P. BAKER, CHARLES LABROLA, JOHN EVANS, G. H. PATT (Ph.D.) (Solarium—Capacity 40).

- 100-1200. *Plastic Surgery* Operative Clinic: Aest. GERALD R. O'BRIEN and STAFF (7th Fl. O.R. 1-4 Capacity 20)

CUMBERLAND HOSPITAL

- 9:00-100. *Fractures and Traumatic Surgery* Operative and/or Nonoperative Clinics: Plating for Femur Neck Fracture. LEO FARBER and STAFF (Auditorium—Capacity 300)

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS

413

Late Results in Fracture of Femur Neck. (Same Rm.)
Traumatic Abdomen. JOSEPH I. ANTON. (Same Rm.)
Ward Rounds with X Ray Studies of Various Types of Fractures. LEO FARRER and STAFF. (Wards 46, 51—Capacity 15)
12:30-1:30. Luncheon at the Hospital.
1:30-2:00. *Fractures and Traumatic Surgery* Nonoperative Clinics. Noonman, Late Results and General Discussion. JOSEPH NEVINS and STAFF. (Auditorium—Capacity 300)
Ward Rounds with Demonstration of Apparatus in Use. JOSEPH NEVINS and STAFF. (Wards 46 51—Capacity 15)
Gadgets and Their Use in Fracture Treatment. JOSEPH NEVINS and STAFF. (Same Rm.)
Head Injuries. Late Results. FRANK TURNER. (Auditorium—Capacity 300)

KINGS COUNTY HOSPITAL

8:30-1:00. *New Surgery* Operative Clinics
Dorsal Cordotomy for Painful Phantom Foot. E. JEFFERSON BROWDER. (B Bldg. O.R. 1-10—Capacity 15)
Sympathectomy for Arterial Hypertension. EVERETT CORADINI. (Same Rm.)
Capsular Fiber Section for Parkinsonism. E. JEFFERSON BROWDER. (Same Rm.)
Dorsal Rhizotomy for Spasticity of Cerebral Palsy. FRANK TURNER. (Same Rm.)
9:00-1:00. *General Surgery* Operative Clinic. JOSEPH TENOPYR and STAFF. (B Bldg. O.R. 1-10—Capacity 15)
9:00-1:00. *Thoracic Surgery* Operative Clinic. Segmental Resection of the Lung. LEW A. HOCHEMRO. (B Bldg. O.R.F.—Capacity 15)
1:00-3:00. *General Surgery* Nonoperative Clinic. Follow up Fractures. JOSEPH TENOPYR. (Main Bldg. Rm. B3—Capacity 50)
1:00-3:00. *Neurosurgery* Nonoperative Clinics
The Cerebellar Hemangioblastomas. EVERETT CORADINI. (Main Bldg. Lecture Rm. 1st Fl.—Capacity 40)
Cysticercus Disease of the Brain. LESTER REED. (Same Rm.)
Surgery for Parkinson's Disease. E. JEFFERSON BROWDER. (Same Rm.)
Management of Fractures of the Spine with Spinal Cord Damage. FRANK TURNER. (Same Rm.)
Subdural Hematoma. RICHARD GRIDER. (Same Rm.)
1:00-3:00. *Thoracic Surgery* Nonoperative Clinics
Lung Abscess as Seen at the Kings County Hospital. ALFRED D. BICUMAS. (F Bldg. Chapel—Capacity 100)
Pneumolysis in Cases of Pulmonary Tuberculosis. EDWIN H. GRIFITH. (Same Rm.)
Some Experiences in the Management of Chronic Empyema. ELOISE E. JOHNSON. (Same Rm.)
Paradoxical Respiration—Its Causes, Consequences and Treatment. LEW A. HOCHEMRO. (Same Rm.)

HOUSE OF ST. GILES THE CRIPPLE

11:00-1:00. *Orthopedic Surgery* Operative Clinic. Abduction Traction Splint for Congenital Dislocation of Hip. C. C. VITALZ. (Roof Clinic—Capacity 60)
Shoulder Fusion for Polio Flail Shoulders, five year Follow-up. Demonstration of Cases. C. C. VITALZ. (Same Rm.)
Follow-up on Shelf Operation, for Congenital Dislocation of Hip. Presentation of Cases. J. GLANZKOPF. (Same Rm.)
Recurrent Clubfoot. Demonstration of Cases Following Resection of Head of Talus Plus Transplantation of Anterior Tibial Tendon. A. OAKER. (Same Rm.)
Demonstration of Cases Following Tereb Major Transplantation for Obstetrical Palsy. C. C. VITALZ. (Same Rm.)

JEWISH HOSPITAL

8:00-10:00. *General Surgery* Operative Clinic. PAUL W. ARCHER and STAFF. (Amph. 1—Capacity 35)
10:00-12:00. *Gynecology and Obstetrics* Nonoperative Clinic. Leo S. SCHWARTZ and STAFF. (Amph. 2—Capacity 35)
Postperal Hematomas of Vulva. PAUL FENKOWITZ. (Auditorium—Capacity 300)
Subcutaneous Heparin in Thromboembolic Disease in Gynecology and Obstetrics. HARRY J. GREENE. (Same Rm.)
A Study of Pelvic Drive in Obstetrics. EDWIN M. GOLD. (Same Rm.)
Hyaluronidase and Infertility. CHARLES BERNBERG. (Same Rm.)
Failed Forceps. LEONARD DACHMAN. WILLIAM POMERANCE. (Same Rm.)
Studies with Gonadotropin. SAMUEL A. WOLFE, IRWIN NEVINS. (Same Rm.)
10:00-12:00. *Gynecology and Obstetrics* Nonoperative Clinic
Diagnosis and Treatment of Solitary Cyst of the Kidney by Aspiration and Injection. ABRAHAM D. SOOAL. (Conference Rm.—Capacity 40)
Treatment of Hydrocoele by Sclerosing Agents. LOUIS H. BARRETT. (Same Rm.)
Periostitis and Ostitis Pubis Complicating Urologic Procedures. ZACHARY R. COTTLER, SAMUEL PARMAS. (Same Rm.)
Structural Uropathy in Children. PERRY KATZEN. (Same Rm.)
uric Acid Phosphatase in the Diagnosis and Management of Carcinoma of the Prostate. LEONARD KIMMEL, PAUL W. ARCHER. (Same Rm.)

KINGS COUNTY HOSPITAL LONG ISLAND COLLEGE DIVISION

8:30-1:00. *General Surgery* Operative Clinics
Gastric Resection. EDWARD P. DUNN. (B Bldg. O.R. 1-10—Capacity 30)
Large Bowel Resection. CHARLES B. JONES. (Same Rm.)
Gall Bladder and Common Duct Exploration. PHILIP E. LEAR. (Same Rm.)
Ligation Patent Ductus Arteriosus. JOHN L. MADDEN. (Same Rm.)
1:45-3:00. *General Surgery* Nonoperative Clinics
Diagnosis and Treatment of Lymphogranuloma Vene reum, Anus Rectum, and Colon. CHARLES B. JONES. (Nurse's Home Classroom—Capacity 50)
Paraduodenal Hernia, Report of Four Cases. PHILIP E. LEAR. (Same Rm.)
Cosmetic Incision for Excision of Benign Breast Tumors and for Supportive Dissection of the Female Breast. GUSTAVO T. DE TOANMA. (Same Rm.)
Tetanus—A Surgical Problem. Experience with Five Hundred Cases in China. PHILLIPS F. GREENE. (Same Rm.)
Gastrojejunocolic Fistula. Six Case Reports. JOHN L. MADDEN. (Same Rm.)
Follow-up Results in Hip Nailing Operations in Femoral Neck. ARNOLD F. SANDLER. (Same Rm.)

LONG ISLAND COLLEGE HOSPITAL

- 9:00-10:00. *Obstetrics and Gynecology* Operative and Non-operative Clinics, and Demonstrations. Members of the staff. (Surg. Amphitheater—Capacity 100)
The Departments of Ophthalmology and Otolaryngology will conduct their programs in the Brooklyn Eye and Ear Hospital.

METHODIST HOSPITAL

- 9:00-10:00. *Obstetrics and Gynecology* Operative Clinics
Vaginal Hysterectomy Total Hysterectomy (Other Operative Procedures to be Scheduled Later) G. H. DAVIS and STAFF (Buckley Bldg.—8th Fl., Mat. O.R. 1-6—Capacity 50)
9:00-10:00. *Obstetrics and Gynecology* Demonstrations
Ball Technique in X-Ray Measurement of Pelvis. J. I. BUTLER, E. GOVAKES. (Maternity Bldg.—Main Fl., Prenatal Clinic—Capacity 40)
Cord Transfusion. B. MATYER. (Same Rm.)

- Inspection of Clinics, Wards and Delivery Room.
RESIDENT STAFF (Same Rm.)
1. Interesting Cases. B. A. G. WENZ.
Maternal Mortality and Morbidity in Obstetrics. I. SEEMAN (Same Rm.)
11:00-12:00. Luncheon at the Hospital.
12:00-1:00. *Obstetrics and Gynecology* Nonoperative Clinic
G. H. DAVIS, Chairman.
Fibroids and Ovarian Tumors Complicating Pregnancy
G. SIMPSON. (Nurse's Auditorium—Capacity 100).
Fetal Mortality in Prolonged Labor. M. C. GARY (Same Rm.)
Leimyosarcoma, Contract with Cellular Myofibrosarcoma. W. G. FLEMING, J. S. HOWE. (Same Rm.)
Abatto Placentae. A. R. BEIL. (Same Rm.)
Manual Removal of Placenta. H. MATYER. (Same Rm.)
Anesthesia in Cesarean Section. H. ACHER, JR. (Same Rm.)
Wedge Resection of Ovary for Polycystic Disease. S. C. HALL. (Same Rm.)

CLINICS IN NEW YORK HOSPITALS

Friday

BEEKMAN DOWNTOWN HOSPITAL

- 9:30-10:45. *Traumatic Surgery* Nonoperative Clinic
Ward Fracture Rounds. ROBERT H. KENYON and STAFF (Wards in groups of 5-6. Total Capacity—30)
9:45-10:00. *Traumatic Surgery* Nonoperative Clinic
Case Presentation of Late Bad Results in Fractures. ROBERT H. KENYON and STAFF (3rd Fl. Annex—Capacity 30)

BELLEVUE HOSPITAL—FIRST (COLUMBIA UNIVERSITY) SURGICAL DIVISION

- 8:00-10:00. *Thoracic Surgery* Operative Clinic. FRANK B. BERRY and STAFF (C & D Bldg., 5th Fl.—Capacity 1)

BELLEVUE HOSPITAL—THIRD (NEW YORK UNIVERSITY) SURGICAL DIVISION

- 8:00-10:00. *Anesthesiology* Demonstration. Anesthesia in Thoracic Surgery. E. A. ROVENSTINE and STAFF (C & D Bldg., 5th Fl.—Capacity 5)

BELLEVUE HOSPITAL—FOURTH (NEW YORK UNIVERSITY) SURGICAL DIVISION

- 8:00-9:30. *General Surgery and Fractures* Operative Clinics. (O.R. K-5 & K-6) ARTHUR McQUELLAN and STAFF (Capacity each operating room, 5)
Thyroid Surgery. ARTHUR S. McQUELLAN (O.R. A)
Stomach Surgery. J. WILLIAM HINTON. (O.R. B)
Intestinal Surgery. LESTER BRIDENBACH. (O.R. C)
Gall-Bladder Surgery. EDWARD V. DICKENSON (O.R. D)
Smith-Petersen Nailing for Fracture of Neck of Femur. KENNETH M. LEWIS (Bones Room K-6)
9:00-10:00. *General Surgery and Fractures*. Nonoperative Clinics (End Results). ARTHUR S. McQUELLAN and STAFF (1 & K Bldg., Stewart Amphitheater—Capacity 100)
Thyroids. ARTHUR S. McQUELLAN
Peptic Ulcers. J. WILLIAM HINTON
Fracture of the Neck of the Femur. KENNETH M. LEWIS
Stricture of Rectum Due to Lymphogranuloma Venereum. LESTER BRIDENBACH
Gall-Bladder Disease. EDWARD V. DICKENSON

BETH ISRAEL HOSPITAL

- 9:00-10:00. *Orthopedic Surgery* Nonoperative Clinic.
IRVING BALDOWITZ and STAFF (3rd Fl. Lecture Rm.—Capacity 30)
10:00-11:00. *Obstetrics* Nonoperative Clinic. EDWIN G. LAMOROCK, SAMUEL J. SCARBOROUGH. (Same Rm.)
11:00-12:00. Nonoperative Clinic. Tumor Clinic. ALBERT FLAUT and STAFF (Auditorium—Capacity 100)

FLOWER AND FIFTH AVENUE HOSPITALS

- 9:00-10:00. *General Surgery* Nonoperative Clinic. Water Balance, etc. FRANCIS D. SPIER, JOHN HENSLY (Auditorium—Capacity 100)
Lymphoid Amino Acids. MICHAEL G. MITCHELL (Auditorium—Capacity 100).
Relationship of Amino Acid Composition of Foods. R. J. BLOCK, H. H. MITCHELL. (Auditorium—Capacity 100)
10:00-11:00. *General Surgery* Nonoperative Clinic. The Prevention of Renal Complications by Therapy with Mixtures of Sulfonamides—or—Phthalyl Sulfonamides in Surgery of Colon. DAVID LERN. (Auditorium—Capacity 100)
11:00-12:00. *General Surgery* Nonoperative Clinic. Presentation of Plans for Resident Training in Surgery. JAMES M. WRIGHT. (Auditorium—Capacity 100)

HARLEM HOSPITAL

- 9:00-10:00. *General Surgery*. Operative and Nonoperative Clinic. Abdominal Catastrophes. B. N. BROWN, A. A. ZINGARD, J. L. WILSON, A. DELL, MAYNARD. (Mills Bldg. O.R.—Capacity 5 or and Gyn. O.R. Women's Pavilion—Capacity 1 & Conference Rm. 5th Fl. Women's Pavilion—Capacity 25). (Ward Rounds will be held on 3d and 5th)
10:00-11:00. *General Surgery* Nonoperative Clinic. Climatological Conference. L. T. WRIGHT, S. WINTHROP and STAFF (Conference Rm. 5th Fl. Women's Pavilion—Capacity 50)

HOSPITAL FOR JOINT DISEASES

- 9:00-10:00. *General Surgery* Operative Clinic. Carcinoma of Colon. Carcinoma of Rectum. Nonoperative Clinic.

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS

415

Intra Abdominal Resection with Anastomosis for Carcinoma of the Rectum. A. J. BELLER. (Surg. Amphitheater—Capacity 50)
 2:00-4:00. *Neurosurgery* Operative Clinic Operations of Brain and Spinal Cord. ABRAHAM KAPLAN (Same Rm.)

HOSPITAL FOR SPECIAL SURGERY
 8:30-12:00. *Orthopedic Surgery* Operative Clinic. Adult Service. PHILIP D. WILSON, R. STEPHENS and STAFF (Main O.R.—Capacity 35)
 2:00-5:00. *Orthopedic Surgery* Nonoperative Clinic (Lecture Hall—Capacity 100)
 Osteoid Osteoma. MILTON HILFELMAN, RAYMOND LEWIS.
 Bone Grafts without Internal Fixation. PETER RIZZO.
 Bridging of Defects of Long Bones of the Extremities. JOHN FLAMAGAKI.
 The Bone Bank. PHILIP D. WILSON
 Spine Fusion with Internal Fixation. L. RAMSEY STRAUSS.
 Problems in the Treatment of Scoliosis. JOHN R. COBB

LENOX HILL HOSPITAL
 9:00-11:00. *Gynecology* Operative Clinic. ROYAL VAN ETTEN and STAFF (O.R. 1, 2 & 3—Capacity each 15)
 11:00-12:00. *Gynecology* Nonoperative Clinic. Hystereotomy Combined Method with Lantern Slides. MORRIS ROODMAN. (Elmhurst Auditorium—Capacity 450)
 2:00-5:00. *Orthopedic Surgery* Nonoperative Clinics Late Results of Unusual Cases
 Osteoarthritis of the Hip in the Aged Treated by Bilateral (Elmhurst Auditorium—Capacity 450)
 Spinal Fusion for the Unstable Spine Giant Cell Tumors of Bone. WALTER SWIFT (Same Rm.)
 Combined Internal External Splitting of Fractures by the Roger Anderson Technique. HENRY JORDAN (Same Rm.)
 Bilateral Epiphysiolysis Capitis Femoris (Slipping of the Upper Femoral Epiphyses). FRANCIS ROTUN. (Same Rm.)
 Inspection of Lenox Hill Brace Shop.

LYING-IN HOSPITAL
 (See New York Hospital)
 MANHATTAN EYE, EAR AND THROAT HOSPITAL

9:30-12:00. *Otolaryngology* Nonoperative Clinic. Demonstration Audiometry; Selection and Fitting of Hearing Aids. Retaining Radical Hearing. WILHELMUS NEEBBERG. (Jones Clinic, 2nd Fl.—Capacity 24)
 12:00-1:00. *Ophthalmology* Nonoperative Clinic. Demonstration Corneal Grafting Technique on Rabbits. H. M. KATZ. (Eye Bank Lab., 10th Fl.—Capacity 12)
 1:00-2:00. *Neurosurgery* Operative Clinic. Facial Nerve Graft Operation and Demonstration of Postoperative Results. T. G. THOMAS. (O.R. 6th Fl.—Capacity 5)
 2:00-4:00. *Otolaryngology* Operative Clinic. Tumors Surgery Preoperative and Postoperative Procedure. R. J. BELLER. (O.R. 7th Fl.—Capacity 5)
 2:00-5:00. *Ophthalmology* Nonoperative Clinic. Orthoptic Clinic. F. C. KURT, JR. E. KRAUZE. (1st Fl. Room—Capacity 12)

MEMORIAL HOSPITAL
 9:00-10:30. *Tumor Surgery* Nonoperative Clinic. End Results Following Abdominoperineal Resection for

Cancer of the Rectum. Treatment of Cancer of the Colon, Management of Squamous Cancer of the Anus and the Rectum. G. E. BINKLEY (Auditorium—Capacity 250)
 10:30-12:00. *Tumor Surgery* Nonoperative Clinic. End Results in the Treatment of Cancer of the Stomach and Esophagus. GEORGE T. PACK, ISABEL M. SHARAGALL. (Same Rm.)
 2:00-5:00. *Thoracic Surgery* Nonoperative Clinic. Asymptomatic Thoracic Tumors. End-Results in Surgically Treated Cases of Carcinoma of the Cervical Esophagus. WATSON. (Same Rm.)
 3:00-4:00. *Tumor Surgery* Nonoperative Clinic. End-Results in Treatment of Bone Tumors. B. L. COLLEY. (Same Rm.)
 4:00-5:00. *Tumor Surgery* Nonoperative Clinic. Discussion. Cancer in Children. Presentation of Followed Cases. H. W. DANZON. (Same Rm.)

METROPOLITAN HOSPITAL
 9:00-12:00. *General Surgery* Operative Clinic. Surgery of Stomach and Duodenum. JAMES M. WHITEHEAD and STAFF (Conference Rm.—Capacity 60)
 Indications. EDWARD J. MCCART. (Same Rm.)
 Vegetation. JAMES M. WHITEHEAD. (Same Rm.)
 Duodenal Closure and Complications. KENNETH C. PRACOCK. (Same Rm.)
 Surgery of Gall Bladder and Pancreas. KENNETH C. PRACOCK. (Same Rm.)
 Retroperitoneal Tumors. KENNETH C. PRACOCK, JOHN SWIDER. (Same Rm.)
 Peritoneal Spaces. JOHN HERRLIN. (Same Rm.)
 2:00-4:00. *Plastic and Reconstructive Surgery* Operative and Nonoperative Clinic. Plastic Clinic. DAVID M. MAYER, JOHN F. FORD. (Main O.R. 1—Capacity 30)

MOUNT SINAI HOSPITAL
 8:30-12:00. *Genitourinary Surgery* Operative Clinic. Kidney Operation. LEO EDELMAN. (Surg. Amphitheater—Capacity 100)
 Nonoperative Clinic. Carcinoma in a Horseshoe Kidney. GORDON D. OPPENHEIMER. (Same Rm.)
 Bladder Neck Obstruction in Young Individuals. MORRIS SWICK. (Same Rm.)
 Peritoneal Insufflation. WILLIAM MENCHER. (Same Rm.)
 Enureals Due to Ectopic Ureter. H. EVANS LITTELL. (Same Rm.)

NEUROLOGICAL INSTITUTE
 (See Presbyterian Hospital)
 NEW YORK EYE AND EAR INFIRMARY
 10:00-12:00. *Otolaryngology* Demonstration Anatomical Specimens. J. SWIFT HANLEY. (Weeks Hall—Capacity 100)
 2:00-4:00. *Otolaryngology* Discussion of Pathology with the routine clinics of the New York Eye & Ear Infirmary will be held as usual during this period. All Fellows of the American College of Surgeons are cordially invited to attend.

NEW YORK HOSPITAL
 9:00-12:00. *Orthopedic Surgery* Operative Clinic. FREDERICK LEE LIEBOWITZ. (10th Fl. O.R., 1 Rm.—Capacity 30)
 2:00-5:00. *Orthopedic Surgery* Nonoperative Clinic. FREDERICK LEE LIEBOWITZ and ASSOCIATES

Segmental Arterial Spasm Associated with Supracondylar Fracture of the Elbow (Case Report) ARTHUR COV 301E. (Rm. F-630—Capacity 70)
 Reconstruction Surgery of the Hand (Lantern Slides) FREDERICK L. LIEBOWITZ (Same Rm.)
 Massive Oolay Bone Grafts for Ununited Fractures. PETERSON WARE (Same Rm.)
 Conservative Treatment of Tibial Fractures of the Tibia. IRVING M. MANSUR (Same Rm.)
 End-Results in Treatment of Fractures of the Neck of the Femur by Moore Nails. NELSON CORVELL (Same Rm.).

1200-1300. *Otolaryngology* Operative Clinic Surgery of the Oropharynx and Nasopharynx THOMAS GAR RICK. (10th Fl. O.R., Rm.—Capacity 30)
 100-300. *General Surgery* FRANK GLENN and STAFF
 The Chemistry of Penicillin and Streptomycin VINCENT DO VONTECH. (College Auditorium, Rm. B-00—Capacity 350)
 Toxicity of Streptomycin W. LUI McDERMOTT (Same Rm.)
 Treatment of Pulmonary Tuberculosis by Streptomycin CARL MUECHENHEIM (Same Rm.)
 Use of Streptomycin in Treating Surgical Pulmonary Tuberculosis. CRANSTON HOWE (Same Rm.)
 Adult Thorax Extract in Wound Healing JAMES DUNWALL (Same Rm.)

NEW YORK HOSPITAL LYING-IN HOSPITAL

900-1000. *Gynecology* Operative Clinic Gynecological Operations by RESIDENT STAFF (GYN O.R. Rm.—Capacity 50)
 1200-1300. *Obstetrics and Gynecology* Operative Clinic Obstetrical and Gynecological Staff Rounds. GORDON DOW LAY and STAFF (Wards—Capacity 3)

NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL

800-1000. *Orthopedic Surgery* Operative Clinic ALAN DE FOREST SMITH and STAFF (O.R. &—Capacity 3)
 30-400. *Orthopedic Surgery* General Orthopedic Clinic HALFORD HALLOCK and STAFF (7th Fl. Assembly Rm.—Capacity 30)

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL

330-400. *General Surgery* Operative Clinic. R. B. LOBBMAN (O.R.—Capacity 3)
 Operative Clinic J. W. HINTON (Surg. Amphitheater—Capacity 3)
 830-1200. *Plastic Surgery* Operative Clinic GUST AVENHART (O.R.—Capacity 1)
 930-1200. *Ophthalmology* Nonoperative Clinic Muscle Anomalies of the Eye with Demonstration of Cases HAROLD W. BROWN (Eye Clinic—Capacity 3)
 30-1200. *General Surgery* Nonoperative Clinic. Thyroid Disease, Including Case Presentations and Discussion of Thyroid Therapy. Carcinoma of the Thyroid, and Anatomical Consideration of the Recurrent Laryngeal Nerve. LOUIS R. SLATTERY RALPH R. MOOREHEAD (Erdmann Auditorium—Capacity 3)
 100-300. *General Surgery* Operative Clinic J. R. KRAMM (O.R. 4—Capacity 1)
 Operative Clinic C. G. HIRT. (Surg. Amphitheater—Capacity 30)
 100-300. *Tumor Surgery*. Operative Clinic. H. W. MYER. (O.R.—Capacity 3)

2200-3200. *Gynecology* Operative Clinic. W. T. DAY. KRUMHOLTZ. (O.R. 3—Capacity 1)

PRESBYTERIAN HOSPITAL

800-1200. *General Surgery* Operative Clinics Surgery of The Large Bowel. Surgery of the Rectum (Amoel). DAVID C. BULL, ROBERT S. GRINDLELL, LOUIS M. ROUSSELOT HENRY S. COOPER. (10th Fl. Main O.R. A II—Capacity each 6)
 Vagotomy for Marginal Ulcer ROBERT H. WITTE (Same Rm.)
 Wiring of Arteriosclerotic Abdominal Aorta. ARTHUR H. BLACKMORE. (Same Rm.)
 100-400. *General Surgery* Nonoperative Clinic. Physiology of Peritonitis. JOHN S. LOCKWOOD. (8th Fl. McCord Amphitheater—Capacity 143)
 Prevention of Wound Infection and Peritonitis with Sulfanilylon and Streptomycin. Case Demonstration EDWARD L. HOWER.
 Laboratory Experiments and Clinical Results with Bacitracin FRANK L. MULLONEY
 Observations on Acute Appendicitis Over a Thirty Year Period at University Hospital. ROBERT A. SCOTT. LINDEN

PRESBYTERIAN HOSPITAL NEUROLOGICAL INSTITUTE

900-1200. *Neurosurgery* Operative Clinic Cases Previously Seen. Clinically at the Monthly Morning Staff Conference. Surgical Staff. (10th Fl. V.L.-O.R. 1—Capacity 2 O.R. 2—Capacity 6)

PRESBYTERIAN HOSPITAL SLOANE HOSPITAL FOR WOMEN

900-1000. *Obstetrics and Gynecology* Nonoperative Clinics: Implantation of Radiators for Carcinoma of the Cervix. JAMES CORCORAN, S. GORDON. (7th Fl. Lecture Rm.—Capacity 4)
 100-200. *Obstetrics and Gynecology* Nonoperative Clinic. Late Follow-up Results in Carcinoma of the Cervix. JAMES CORCORAN (Same Rm.)
 100-300. *Obstetrics and Gynecology* Nonoperative Clinic Trends in the Treatment of Uterine Carcinoma. HOWARD C. TAYLOR, JR. (Same Rm.)

PRESBYTERIAN NEW YORK ORTHOPEDIC HOSPITALS

Fracture Service
 900-1000. *Fractures and Traumatic Surgery* Nonoperative Clinic. Fracture Service Grand Rounds and Conference. FRACTURE SERVICE STAFF (Fresh Hop Ortho Wards, 10th Fl. W.—Capacity 30)
 100-400. *Fracture and Traumatic Surgery* Nonoperative Clinic. Role of Sympathetic System in the Surgery of Trauma. STEPHEN S. HUNTER. (Rm. 47 6th Fl. Phys. & Surg. Bldg.—Capacity 60)
 Use of Amino Acids in Maintaining Nitrogen Balance. SIDNEY C. WALKER. (Same Rm.)
 The Treatment of Shock Colloid. 10th Trauma JOHN SCUDDER. (Same Rm.)

ROOSVELT HOSPITAL

900-1000. *General Surgery* Nonoperative Clinics: Tumors of the Stomach With Colored Photographs of Specimens. HOWARD A. PATTERSON. (Conference Rm. 1—Capacity 30)
 Demonstration of Stomach Tumor Specimens. WALLACE BRAMMER. (Conference Rm.—Capacity 30)
 Some Late Results of Conservative Treatment in Vascu-

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS

417

lar Problems. GRANT P. PENNOVER. (Conference Rm. 1—Capacity 50)
The Observed Effect of Various Drugs on Intestinal Activity. Motion Picture Demonstration. DAVIN M. WEXLER. (Conference Rm. 1—Capacity 50)

ST VINCENT'S HOSPITAL

9:00-12:00. *General Surgery* Operative Clinics and Demonstration Cases of Trauma Fractures. C. J. MAQUETTE, FRANK CONWAY, LOUIS SAMMAN, JOHN A. FALLON, MAURICE O'SHEA. (O. R. A & B—Capacity each 5 O. R. C—Capacity 10)

9:00-12:00. *General Surgery* Tumor Clinic and Follow-up. Auditorium—Capacity 150
9:00-12:00. *Anesthesiology* Nonoperative Clinic. The Results of Conservative Treatment of Acute Head Injuries. FRANKLIN ROBINSON. (Nurse's Lecture Rm.—Capacity 60)

12:00-4:00. *Pathology* Nonoperative Clinic Display of Fresh Pathological Material. Display and Demonstration of Systemic Diseases by Kodachrome Slides and of Fixed Specimens. ARTHUR ROTTINO and ASSOCIATES. (Same Rm.)

SLOANE HOSPITAL FOR WOMEN (See Presbyterian Hospital)

U. S. MARINE HOSPITAL (STATEN ISLAND)

10:00-12:30. *General Surgery* Nonoperative Clinic Esophageal Hypertension—Combined Medical, Surgical, and Anesthesiology Presentation. H. L. SKINNER, C. L. HERBERT and STAFF. (Doctor's Staff Rm.—Capacity 75)

12:30-1:00. Luncheon at the Hospital
1:00-2:00. *General Surgery* Operative Clinic Dorsolumbar Sympathectomy—Intrathecal Anesthesia. H. L. SKINNER and STAFF. (General O. R.—Capacity 10)

1:00-3:00. *Genitourinary Surgery* Nonoperative Clinic Genitourinary Surgical Ward Rounds. CHARLES FERGUSON and STAFF. (Ward E.F. 6—Capacity 20)

VETERANS ADMINISTRATION HOSPITAL

9:00-12:00. *General Surgery* Operative Clinic. CARMES WEEKS, JOHN E. SULLIVAN. (Bldg. D 12th Fl. 1 Rm.—Capacity 10)

9:00-12:00. *Thoracic Surgery* Operative Clinic. WALTER CHAMMALL, AARON HUMMELSTEIN, RICHMOND MOORE. (Bldg. D, 12th Fl. 1 Rm.—Capacity 10)

9:00-12:00. *Orthopedic Surgery* Operative Clinic. SYDNEY EICHENMOLZ, ROBERT PATTERSON, FRANK E. STERN. (Bldg. D, 12th Fl. 1 Rm.—Capacity 10)

9:00-12:00. *Head and Neck Surgery* Operative Clinic. EDGAR L. FRANKEL. (Bldg. D, 12th Fl. 1 Rm.—Capacity 10)

9:00-12:00. *Plastic Surgery* Nonoperative Clinics Plastic Surgery. HERBERT CONWAY, CLARENCE R. STRAATMAN, CONNELL J. KRAEHL, ROBERT H. CLIFFORD and RESIDENT STAFF
Cases Demonstrating the Use of Large Abdominal Crossed Leg Flaps. (Bldg. A, 3rd Fl.—Capacity 200 Rm.)

Plastic Surgery in Cancer of the Head and Neck. (Same Rm.)
9:30-12:30. *General Surgery* Nonoperative Clinic Medical Rehabilitation Clinic. HARRY KIEHLER, KARL HANFUDER, IRWIN D. STEIN, HERMANN STOLL, and JACOB BYER. (Bldgs. B, C, & F Ground Fl.—Capacity 20)

11:00-12:30. *General Surgery* Nonoperative Clinic: Thoracolumbar Sympathectomies. CARMES WEEKS. (Bldg. A, 3rd Fl.—Capacity 200)
12:30-3:30. *Radiation Therapy* Nonoperative Clinic Exhibit and Presentation Bronchogenic Carcinoma—Analysis of Diagnosis and Therapy with End-Results. A Study of 600 Cases. ARTHUR SIEGEL, BERNARD ROSEN, JOSEPH STEIN and RESIDENT STAFF. (Bldg. A, 3rd Fl.—Capacity 200)

3:30-5:00. *Anesthesiology* Nonoperative Clinics Conference Endotracheal Anesthesia. Electrocardiographic Changes during Intrathoracic Surgery. EMORY ROYENITZ, HAROLD BISHOP, CHARLES BORSTEIN and RESIDENT STAFF

EXHIBITS

(Bldg. A, 3rd Fl.)

Anesthesia Section
Bronchogenic Carcinoma
Review of 600 Cases
Intracranial Neoplasms
Residency Training Program
Organization of Surgical Division
Results of Vagus Resection
Pathology Section
Medical Illustrations
Laboratory
Plastic Surgery
Prosthetic Appliances

WOMAN'S HOSPITAL

8:30-12:30. *Obstetrics and Gynecology* Nonoperative Clinics ALBERT ALDRIDGE and STAFF. (4th Fl. Conference Rm.—Capacity 75)
Treatment of Neoplasms of the Female Genital Tract.
Management of Birth Injuries and Uterine Displacement.
Diagnosis and Treatment of Obstetric Complications.
End Results of Treatment of These Conditions Will Be Discussed.
During the course of the morning the routine for training of Residents in Gynecology and Obstetrics will be outlined.
The pathologist will give demonstrations of obstetric and gynecologic pathological specimens.

CLINICS IN BROOKLYN—LONG ISLAND HOSPITALS

Friday

CUMBERLAND HOSPITAL

9:00-12:00. *General Surgery* Operative Clinic Cancer and Prostate. HOWARD T. LANGWORTHY and STAFF. (O. R. 1 & 3—Capacity 20)
Orchiectomy for Prostatic Metastases. Late Results. LEO DREZLER. (Auditorium—Capacity 300)

Cancer of Bladder with Transplantation of Ureter. Late Results. LEO DREZLER and STAFF
9:00-12:30. JOSEPH J. ANTON
9:00-3:00. *Nonoperative Clinic*. Late Results in Thrombophlebitis and Phlebotrombosis. WARD CHILLY Tumors in Children. HERMAN CHACHACH.

Convulsions During Anesthesia. Lat. Results. I video
M. PALLIN

KINGS COUNTY HOSPITAL

- 9:00-1:00. *Gynecology* (Kings County Division) Operative Clinics. GARLICK, MCGOLDRICK and MUELLER. (B Bldg. O R. 1-10—Capacity 3)
- 9:00-1:00. *Thyroid Surgery* Operative Clinic Thyroidectomy. ARTHUR PERUDONT. (Same Rm.)
- Nonoperative Clinic: Use of Propyl Thiouracil. (T follow in O R.) (Same Rm.)
- 9:00-1:00. *General Surgery* Nonoperative Clinic JOHN F. RAYCHOTT and STAFF
- Cholecystectomy in the Acute Gall Bladder as Compared with Cholecystectomy in the Chronic Gall Bladder. IRWIN P. TRAM. (O P D Bldg. Lecture Rm.—Capacity 50)
- Use of the Miller Abbott Tube As an Aid in Intestinal Surgery. JOHN F. RAYCHOTT. (O. P. D. Bldg., Lecture Rm.—Capacity 50)
- Review of Gastric and Duodenal Surgery. HARVEY F. POTTER. (Same Rm.)
- Fracture of the Neck of the Femur—Five year Study with Follow-up. VINCENT S. MAURO. (Same Rm.)
- Case Report. Congenital Idiopathic Distention of the Common Bile Duct. JOHN F. RAYCHOTT. (Same Rm.)
- Review of Amputations of the Lower Extremities. THOMAS W. HINES. (Same Rm.)

Review of Acute Appendicitis. PETER FRIEL. (Same Rm.)

Review of Large Bowel Surgery. BERNARD J. FRIEDL. (Same Rm.)

Therapy of Peripheral Vascular Disease. C. HIRSH. ROSEN. (Same Rm.)

2:00-5:00. *Gynecology* Nonoperative Clinic: Follow-up of Gynecologic Malignancies. JOSEPH MCGOLDRICK. (Main Bldg., Rm. B-3—Capacity 50)

LONG ISLAND COLLEGE HOSPITAL

- 9:00-1:00. *General Surgery*
- Operative Program. LEO GOSTICK and STAFF. (Surg. Amphitheater—Capacity 100).
- Nonoperative Clinic: Fractures and Other Trauma. S. POTTER BARTLEY HAROLD LARON. (Surg. Amphitheater—Capacity 50)
- Nonoperative Clinic: Diagnostic and Therapeutic Nerve Blocks. PAUL AMERRO. (Surg. Amphitheater—Capacity 100).
- The Departments of Ophthalmology and Otolaryngology will conduct their programs at the Brooklyn Eye and Ear Hospital.

METHODIST HOSPITAL

- 9:00-1:00. *Tumor Surgery* Nonoperative Clinic: Tumor Clinic (Late Results). PIERRE A. RICHARD, Moderator and Hospital Staff. (Nurse Auditorium—Capacity 500)

COLLECTIVE REVIEW

THE DEVELOPMENT OF THE CONCEPT OF ANTISEPSIS AND ASEPSIS FROM LISTER TO WORLD WAR II

H WINNETT ORR M.D., F.A.C.S., Lincoln Nebraska

MANY surgeons before Lister had observed the primary healing of wounds. Some of them had envisioned universal recovery from traumatic injuries and surgical operations if only the cause of local inflammation and the systemic hospital fevers could be found. But most prelisterian surgeons had become reconciled to pyemia, septicemia and hospital gangrene as being inevitable except in those patients who by some providential dispensation over which the surgeon had no control, escaped. Some thought the so-called hospital diseases were caused by miasmas in certain neighborhoods by the polluted air in the vicinity of graveyards or where there had been much disease as in hospitals. The outstanding surgeon John Erichsen (one of Lister's teachers) advocated the tearing down or burning of hospitals in which erysipelas and gangrene were prevalent. He said it was as impossible to rid them of contagion as to stop the fermentation in a cheese.

The Lister antiseptic system did not spring all at once fully developed from the mind of the inventor. Like most medical and surgical discoveries the antiseptic system developed gradually and not even always consistently during the years both before and since Lister promulgated his idea in 1867. What Lister saw that others did not see was that chemicals might be employed to keep the out of injuries and surgical wounds. He did not at first employ a chemical in the ordinary wounds and sores that every doctor and every surgeon sees in his practice. In a course of lectures that he

gave at the University in Glasgow he referred to the fact that in private practice he was still using the water dressing. But he said that he used carbolic acid in the hospital not so much for the benefit of the sores themselves as for producing as much purity as possible in the hospital wards to keep the causes of putrefaction out of wounds and to limit putrefaction when present to the original victims.

In referring to this matter Lister indicated that he foresaw the time when with clean wounds it might be possible to sew them up and have them heal by primary intention that is, without any wound complications inflammation, or suppuration whatever. Lister set this idea aside however at that time for the reason that he could not imagine the use of any chemical to sterilize the wound or to make the wound sufficiently clean for primary closure without too much damage to the tissues. Lister had constantly before him the cases in which extensive suppuration inflammation, and other hospital diseases (to which we have referred) were present. He realized that to sew up or close wounds might cause surgical complications and deaths and that this danger could never be disregarded if suppuration fermentation and putrefaction had not been avoided at the beginning.

On the other hand Lister feared the effects of antiseptics applied directly to the wound surface. He had not arrived at the point where he could foresee or understand the prevention of surgical infections by aseptic methods, that is, the keeping out of germs by sterile dressings, rubber gloves,

is only an adaptation and extension of normal nu-
trition.

With the great improvement in results that took
place in surgical practice generally after the anti-
septic system became popular it is not astonish-
ing that other useful surgical expedients came to
be neglected. One felt that with infection under
control results were so much better that they
were good enough. Also surgeons, as doctors often
do, fell into the error of supposing that every im-
provement in the patient's condition following the
use of the antiseptic was due to the chemical agent
employed. They forgot, as Gamgee and others
had pointed out that

'Life and putrefaction are not correlative, but
antagonistic and in proportion as the surgeon
finds and economises the attributes of life he will
find himself independent of those changes which
are inherent to decaying organic matter whether

pression dressing to which he had already given
the name of hyponarthesis. Gamgee reported a
series of more than 100 general surgical cases treat-
ed without using Lister's method and with less
than 3 per cent mortality. He referred to the
simple methods of operation and dressing by Barn-
Larrey who did 14 shoulder amputations in the
battle field with only 2 deaths. This was in con-
tention in the fact that such methods as com-
pression or wound protection drainage, and rest
gave patients an opportunity to recover before the
days of antiseptics. At the same time it must be
remembered that in Lister's own wards at Glas-
gow before antiseptic methods were employed
and when irrigations frequent dressings and sep-
tas were general the death rate in all ampu-
tations even fingers was from 50 to 75 per cent.

It was very easy for Gamgee to adjust and adapt
the wound dressing method with which he was al-
ready familiar and which he had been teaching
to the germ theory of wound infection and putre-
faction. This is indicated as well as anywhere in
Gamgee's 'Treatment of Wounds and Fractures,'
published in London in 1883. In an article
2 p 813 (Philadelphia ed. 1886) he amplified
and clarified his views somewhat further to indi-
cate exactly where he stood on the Lister antisep-
tic method. Gamgee wrote 'Antiseptics have so
far only been mentioned incidentally but the
materials recommended for the wound-dressings
such as borax and glycerine tincture of benzoin
styptic colloid, and collodion are in eminent de-
gree antiseptic. The question in wound treatment
is not one of antiseptics or no antiseptics but of
the form and proportion in which they should be
employed in particular conditions. The great an-
tiseptic is life. The living tissues have a natural
preservative power which if guarded and con-
served by the surgeon on physiological principles
offers the surest guarantee for healthy repair which

antiseptic preparation of the skin, covering of the surgeon's nose and mouth and the like for the better protection of the patient at the time of operation.

Lister explained, upon the occasion of one of these lectures (about 1870) that even in those days the surgeon did not undertake the removal of a tumor if he knew beforehand that he would be unable to close the wound and close the skin after the operation. Surgeons thought that any open wound was dangerous for the patient. Lister told of an experience in which he had excised a small epithelial cancer from an old lady's scalp: the edges of the wound could not be brought together. "Putrefaction" nearly caused her death but by good fortune she recovered.

He said "I determined from that very time to use antiseptic dressings to every raw surface." This indicated that, even then, he considered irritation of the wound surface by carbolic acid preferable to risking the danger of infection after operation. He did not appreciate fully the dangers of secondary infection at the time of changing dressings,

and the fact that such infections did occur (then as now) had not made its full impression upon him.

Regarding his view of the future and the possibility of performing aseptic operations, his exact words were as follows: "But then you might say theoretically that if you have some germ poisoner which will prevent decomposition and at the same time which would not irritate the surrounding tissues, we might sew up the edges of the wound closely together. Do we know of any material which would kill the germs without irritating the tissues? If we had such a substance we might then sew up the wound and apply some antiseptic dressing and reckon upon union by the first intention. That is theoretically the correct treatment of incised wounds. Have we any such antiseptic? No!" That was Lister's answer in 1870 and it is my answer now.

Regarding compound fractures, Lister said, "Fifteen cases of compound fracture were treated by my last house surgeon Dr. (Sir Hector) Cameron, and all of these men or women are living with all their limbs on." And in another place he said that it was worse than useless to syringe out a compound fracture with carbolic acid and not apply an antiseptic dressing. The effect of the acid would pass away in a few hours and the parts would be exposed to a worse irritation than if they had never been syringed with the antiseptic. Amputation at first would have been better.

This was the Listerian teaching. It was perfectly clear, perfectly comprehensible, and perfectly true, but it has not been understood or followed entirely by many of those who have undertaken the primary or the secondary closure of infected wounds. Those successes which have occurred following primary closure have not been attributed, as they should have been, to the resistance and powers of recovery in the patient, but to the agent employed, whatever that chemical happened to be.

Mr. Sampson Gamgee, a Lister contemporary in London, was one of those who protested against the adoption of the antiseptic method. He said that one may as properly speak of homeopathic medicine as of antiseptic or any other special kind of surgery. Gamgee was a well-trained surgeon who had visited other countries and knew their methods. He had seen Maisonneuve at the Hotel Dieu in Paris using antiputrescent lotion of 1 per cent carbolic acid to control wound infection. Debat said that Maisonneuve had used this since 1861 (6 years before Lister) constantly for wounds after an original demonstration by Debat himself. Gamgee was an advocate of the infrequent com-

Lister began the antiseptic treatment of wounds with carbolic acid. Some of his early results were as good as any he or his successors ever attained. A point to which it seems important to call attention in this article is that Lister's later laboratory experiments with germ cultures, fermentation, and antiseptic chemicals had a confusing and distracting effect even upon him in his further application of the 'antiseptic principle' of wound protection which was his original idea.

To convey an impression of surgery prior to the introduction of the antiseptic method is almost impossible. It is important, however, to know something of what was happening in practice and in hospitals if we are to appreciate the great change that occurred. Some of our popular histories as well as many heavy surgical volumes convey the sad story of those times. Ralph Major's "Fatal Partners—War and Disease" gives us an idea as

to what the infectious diseases were doing before we understood the relationship between germs and the epidemics of communicable disease.

In a way the surgery of the prelisterian era was a plague in itself. There were thousands of post-operative deaths from gangrene, erysipelas, tetanus, and gas bacillus infections. Surgery directly responsible for most of these was revolutionized just as was the control of tuberculous, typhoid fever and cholera, by Pasteur, Lister and Koch.

One of Lister's biographers, Cuthbert Dule pointed out that when a surgeon in those days had performed successfully the simplest operation, such as the amputation of a finger, he knew it might be followed by dangerous and even fatal consequences. Professor Volkmann at Halle made the remark that, before Lister when a surgeon closed the wound, he was "like a husbandman, having sown his field waits with resignation for what the harvest may bring and reaps it fully conscious of his own impotence against the elemental powers which may pour down upon him rain, hurricane, and storm."

One of the earliest effects of the introduction of the antiseptic system was to call attention to the fact that while deaths caused by sepsis and infection were common following operations in private homes, the results were far worse when patients were operated upon in hospitals. We know now that infection was carried from one patient to another and that tetanus, erysipelas, gangrene, and septicæmia were communicated by the patients or their attendants. Intramural epidemics of these septic diseases became so serious that the tearing down of buildings and their replacement were urged as the only method to get rid of the infectious plagues.

In 1861 the death rate after amputations in all the Paris hospitals was as high as 3 deaths among every 5 operations. Although he was one of the severest critics of the antiseptic method, Sir James Simpson, speaking on the same program with Lister at Belfast in 1867, asked the public health section of the National Association for the Promotion of Social Sciences the following question: "To what extent are hospitals as in general at present constituted banes or blessings, and how can they be so changed as to convert them from the former to the latter?" He suggested that stone and marble palaces should be abandoned and that iron or wooden villages should be built in their place. He thought that in this way the new buildings would be free from the polluted air which he supposed caused the infections and surgical diseases to which all such hospitals were subject at that time.

Fig. 5. Dr. Seguin was Dr. Ridlon's preceptor in New York before 1890.

Even as late as 1874 Sir John Erichsen suggested that hospitals should be torn down and rebuilt periodically. He said "Once a hospital has become incurably pyaemia stricken it is as impossible to disinfect it by any known means as it would be to disinfect the crumbling wall of the ant that have taken possession of it, or an old cheese of the maggots that have been generated in it."

It is for these reasons that Lister chose "The Effect of the Antiseptic System upon the Salubrity of Hospitals and Hospital Wards" as the title for one of his early papers.

In 1853 when Lister arrived at the University of Edinburgh to begin his graduate study of surgery with Professor James Syme, Syme was at the height of his professional career. His reputation for surgical skill, as a teacher and for exceptional personal qualities had extended not only through out the British Isles but into Continental Europe and America as well.

In surgery as in other ways, Syme was a militant crusader. He could be and often was a general host to friends in his home but in public and in the principles and methods which rested upon his fine training and his experience, and he was against all tendencies or teachings which he considered to be less worthy of consideration.

Lister had been sent to Edinburgh with a letter from William Sharpey, a great friend of Professor Syme. As a student Sharpey had studied at both Edinburgh and Paris and it was in Paris that he formed a lifelong friendship with Professor Syme.

Lister's first paper at University College, London written under Sharpey's supervision was on the conduct of the iris of the eye and the physiology of vision. It is now interesting to remember that in this paper Lister commented upon the fact that the methods employed had served to delay the decomposition of the tissues upon which he was engaged.

When Lister became house surgeon to John Eric Erichsen in London (1852) he had charge of his first patients. Erichsen had written and continued to write some of the best literature in the entire history and development of surgery. One of his special anxieties was with regard to hospital gangrene, wound infection and blood poisoning after injuries and operations.

It was generally believed by surgeons that putrefaction and gangrene were occasioned by the action

(The) refers to the few former held that maggots and other small animals originated the process in decomposing or putrefying organic matter. Not only Pasteur with his germ theory and his demonstrations as to the continuity of life in bacterial cultures, but Koch with his ideas and other scientific workers, spent years in proving that all living things have living parents.

cess of the oxygen in the atmosphere to the wound. Lister made it his special study to observe and compile data upon surgical complications as they occurred and to note conditions or materials that seemed to affect the course of the various kinds of inflammation and surgical disease.

The circumstances under which Lister saw his first surgical operations thus accounted in considerable measure for his interest in the causes and effects of inflammation. The use of ether and chloroform was just becoming general and patients consented to have operations performed because they could be done without pain and without some at least, of the risks to which they had been accustomed. Surgeons themselves were much more courageous in undertaking operative procedures about

Lister began the antiseptic treatment of wounds with carbolic acid. Some of his early results were as good as any he or his successors ever attained. A point to which it seems important to call attention in this article is that Lister's later laboratory experiments with germ cultures, fermentation and antiseptic chemicals had a confusing and distracting effect even upon him in his further application of the "antiseptic principle" of wound protection, which was his original idea.

To convey an impression of surgery prior to the introduction of the antiseptic method is almost impossible. It is important, however to know something of what was happening in practice and in hospitals if we are to appreciate the great change that occurred. Some of our popular histories as well as many heavy surgical volumes convey the sad story of those times. Ralph Major's *Fatal Partners—War and Disease* gives us an idea as

to what the infectious diseases were doing before we understood the relationship between germs and the epidemics of communicable disease.

In a way the surgery of the prelisterian era was a plague in itself. There were thousands of post operative deaths from gangrene, erysipelas, tetanus, and gas bacillus infections. Surgery directly responsible for most of these, was revolutionized, just as was the control of tuberculosis, typhoid fever and cholera by Pasteur, Lister and Koch.

One of Lister's biographers, Cuthbert Duke, pointed out that when a surgeon in those days had performed successfully the simplest operation, such as the amputation of a finger, he knew it might be followed by dangerous and even fatal consequences. Professor Volkmann at Halle made the remark that before Lister when a surgeon closed the wound, he was "like a husbandman having sown his field waits with resignation for what the harvest may bring and reaps it fully conscious of his own impotence against the elemental powers which may pour down upon him rain, hurricane, and storm."

One of the earliest effects of the introduction of the antiseptic system was to call attention to the fact that while deaths caused by sepsis and infection were common following operations in private homes, the results were far worse when patients were operated upon in hospitals. We know now that infection was carried from one patient to another and that tetanus, erysipelas, gangrene and septicemia were communicated by the patients or their attendants. Intramural epidemics of these septic diseases became so serious that the tearing down of buildings and their replacement were urged as the only method to get rid of the infectious plagues.

In 1861 the death rate after amputations in all the Paris hospitals was as high as 3 deaths among every 5 operations. Although he was one of the severest critics of the antiseptic method, Sir James Simpson, speaking on the same program with Lister at Belfast in 1867 asked the public health section of the National Association for the Promotion of Social Sciences the following question: "To what extent are hospitals as in general at present constituted banes or blessings, and how can they be so changed as to convert them from the former to the latter?" He suggested that "stone and marble palaces should be abandoned and that iron or wooden villages should be built in their place. He thought that in this way the new buildings would be free from the polluted air which he supposed caused the infections and surgical diseases to which all such hospitals were subject at that time.

"(1) That these germs must be prevented from getting into wounds during and after operations, and that they must be killed if possible outside the wound

(2) That if they have succeeded in getting into a wound before the case is seen by the surgeon as in compound fracture they must be killed if possible before they have had time to spread and secure a footing and further germs must then be prevented from entering the wound afterwards.

"These principles still hold the field whatever methods are employed to carry them out, and they are not likely to be given up till some means have been devised for protecting the body against all germs which may enter it, and this is certainly not within sight at the present time. (25—Pp 50-51) (New chemical techniques have usually contributed complications, false confidence and confusion H W O)

Lister's first operation was the opening of a psoas abscess, and it is interesting to note how he did it. (1) He first prepared a mixture of one part of carbolic acid to three parts of boiled linseed oil. A piece of lint about six inches square was soaked in this solution and placed over the site of operation for some time before it was performed the instruments were also placed in carbolic oil, and naturally the surgeon's and assistants' fingers became coated with it. When everything was ready the piece of lint was raised at one side and an incision was quickly made into the abscess the lint was then allowed to fall back over the wound and the pus was squeezed out of the abscess under cover of the oiled lint, and finally a strip of the oiled lint was pushed through the opening into the abscess in order to keep the wound from closing

(1) I cannot find the exact date of this operation but I think that it was early in 1867

Several of Lister's biographers have pointed out that Lister endeavored from the beginning to employ chemicals for the purpose of excluding germs from wounds, and this is true. The use of carbolic acid to exclude infection was the fundamental conception with which Lister inaugurated his antiseptic system. He was so emphatic on this point that when Von Bergman and his followers began to advocate the aseptic method it was supposed by many that there had to be two schools of surgery one the antiseptic, in which chemicals were used entirely and the other the aseptic, in which nonantiseptic solutions for washing germs away and boiling and heat with sterilized dressings were employed as the technical agents.

One may suppose that this situation was partly responsible for Lister's further studies of germicides and germicidal dressings while some who

held themselves out to be really opponents of the Lister method made their campaign on the side of the asepticists. It is easy now for us to see that these two schools had much in common but the antisepticists are still responsible as they were in Lister's time for a misunderstanding of the proposition that to protect a patient against infection and especially against mixed infection is one of the greatest services that a surgeon can render in or out of the operating room.

That Lister did become confused by both friends and enemies is indicated by his reaction to the early German demand "Fort mit dem Spray, and by the fact that both British and American visitors saw the tendency away from his original ideal and toward attempts to cure wound infection by new and different changes in technique. The following was from a Philadelphia surgeon

Most of Lister's contemporaries did not recognize the fact that he was contending for a principle in surgery they looked upon his innovations as nothing more than the introduction of some new

the dangers of which otherwise the patients knew very little.

Lister saw these operations at University College Hospital in London. While many of them were performed with considerable dexterity on the part of the surgeons, there were still the surgical complications which always prevailed in every hospital after injury or operation.

It does seem strange that Lister alone of those who witnessed the after effects of operations and the surgical diseases of that period should have arrived at an understanding of these surgical complications. As it was, he had studied the problem sufficiently so that the discovery of germs gave him, first, the cue to the use of antiseptics for the prevention of the 'hospital diseases.'

As Sir Clifford Allbutt said, 'Lister was sitting on the heights and watching there alone for Pasteur's discovery

From the point of view of the exclusion of the causes of putrefaction Lister's exposition even

as reported by Godlee should, if it had been understood by surgeons generally have saved much of the confusion and many of the erroneous practices (including the Carrel-Dakin method) of the last 70 years. Godlee said 'With carbolic acid as the antiseptic he (Lister) introduced what he called a 'protective. This was a material (mactintosh) unstimulating in itself and impervious to carbolic acid. The intention was to place a piece of the protective, of limited size, in immediate contact with the wound, in order to protect it from the imtation of the dressing which, however overlapped the protective widely on every side.

Lister was using the protective in 1869 but he first described it in 1870 in a clinical lecture at Edinburgh in which he thus explained its meaning and purpose 'Of all those who use antiseptics in surgery I expect that I apply them least to the surface of the wound. After the first dressing, the object which I always aim at is to have the material in contact with the exposed tissues approximate as closely as possible to the perfectly bland and neutral character of the healthy living textures. If you consider the circumstances of a simple fracture, which you cannot too often call to mind if you wish to keep your ideas clear and right upon this subject—if you remember how the severe contused internal wound, with the interstices of the mangled tissues loaded with extravasated blood, recovers quickly and surely under the protection of the unbroken integument, it is plain that all that is required in an external wound is to guard it against the disturbing influence of (any) external agency. The injured tissues do not need to be 'stimulated or treated with any mysterious specific' all that they need is to be left alone.

"Our 'protective, then should be a material unstimulating in its own substance, and impervious to carbolic acid. At the same time it must be insoluble in the discharges, and sufficiently supple to apply itself readily to the part.

"These principles' will be found to apply whatever be the materials used for carrying out the antiseptic system. An antiseptic to exclude putrefaction with a protective to exclude the antiseptic will, by their joint action keep the wound from abnormal stimulus" (51—2 ed. pp. 216-217)

Perhaps further clarification of Lister's original ideal is unnecessary but here is a statement from the long time associate who was the 'Boswell of his entire professional career' (25—Pp. 10-11) 'Lister's application of Pasteur's statements

the dangers of which otherwise the patients knew very little.

Lister saw these operations at University College Hospital in London. While many of them were performed with considerable dexterity on the part of the surgeons, there were still the surgical complications which always prevailed in every hospital after injury or operation.

It does seem strange that Lister alone of those who witnessed the after effects of operations and the surgical diseases of that period should have arrived at an understanding of these surgical complications. As it was, he had studied the problem sufficiently so that the discovery of germs gave him, first, the cue to the use of antiseptics for the prevention of the "hospital diseases."

As Sir Clifford Allbutt said "Lister was sitting on the heights and watching there alone" for Pasteur a discovery

From the point of view of the exclusion of the causes of putrefaction Lister's exposition even

as reported by Godlee should, if it had been understood by surgeons generally have saved much of the confusion and many of the erroneous practices (including the Carrel Dakin method) of the last 70 years. Godlee said "With carbolic acid as the antiseptic he (Lister) introduced what he called a 'protective.' This was a material (mackintosh) unstimulating in itself and impervious to carbolic acid. The intention was to place a piece of the protective, of limited size, in immediate contact with the wound in order to protect it from the irritation of the dressing which however overlapped the protective widely on every side.

Lister was using the protective in 1869 but he first described it in 1870 in a clinical lecture at Edinburgh in which he thus explained its meaning and purpose "Of all those who use antiseptics in surgery I expect that I apply them least to the surface of the wound. After the first dressing, the object which I always aim at is to have the material in contact with the exposed tissues approximate as closely as possible to the perfectly bland and neutral character of the healthy living texture. If you consider the circumstances of a simple fracture which you cannot too often call to mind if you wish to keep your ideas clear and right upon this subject—if you remember how the severe contused internal wound with the intensities of the mangled tissues loaded with extravasated blood, recovers quickly and surely under the protection of the unbroken integument, it is plain that all that is required in an external wound is to guard it against the disturbing influence of (any) external agency. The injured tissues do not need to be stimulated or treated with any mysterious specific all that they need is to be let alone

"Our 'protective' then should be a material unstimulating in its own substance and impervious to carbolic acid. At the same time it must be insoluble in the discharges, and sufficiently supple to apply itself readily to the part.

"These principles will be found to apply what ever be the materials used for carrying out the antiseptic system. An antiseptic to exclude putrefaction, with a protective to exclude the antiseptic will by their joint action keep the wound from abnormal stimulus" (51—2 ed pp. 216-217)

Perhaps further clarification of Lister's original ideal is unnecessary, but here is a statement from the long time associate who was the "Borrell" of his entire professional career (25—Pp. 10-11)

"Lister's application of Pasteur's statements was

Protection of the tissues and exclusion of infection—the details of technique (1170)

gist and pathologist of his day but for a laboratory man he had an extraordinary appreciation of the clinical side of his work. The combination of these two in European study was an incident of the greatest importance especially as they spent some time on Lister and his work. When they returned to America they brought back cultures from the Lister laboratory which as Dennis said satisfied him for the first time that there was a germ cause of disease and wound infection. Dennis persuaded Mr. Andrew Carnegie to build and equip a laboratory not only for this study but for instruction at Bellevue and this was the first of its kind in this country.

Upon the occasion of the visit of Dennis and Welch to Guy's Hospital in London they found the great change that had already taken place in the percentage of deaths after compound fractures and wound infection. The reduction in some classes of operations and infected injuries was from 65 per cent down to an actual zero. Dennis confessed that for his own part he remained skeptical of the germ theory of inflammation until the Carnegie laboratory gave him the opportunity to work out the problem for himself. He concluded his report, as follows:

"The reduction of the death rate from 68 per cent, which half a century ago was considered a brilliant achievement, and a result which was thought worthy of publication to that of a cipher represents what surgery has done for the amelioration of human suffering and the preservation of life. Humanity indeed, owes a debt of gratitude to the science of surgery which has annihilated pain and suffering and has preserved and prolonged human life. For this great work—to the former (Pasteur) as the discoverer of the means, and to the latter (Lister) as the one who applied the discovery to surgery the profession are indebted. Surely their names must ever be associated with the march and progress of the grandest profession in the world. (33—Vol. 1 pp. 422-423)

The drift away from the Lister ideal was indicated by many incidents such as the following:

In 1886 after stating clearly the conception of exclusion "Watson Cheyne diverts at once to some of the antiseptic techniques that were and have continued to be violations of the original Lister idea.

He said, In the Listerian Method the object is to prevent the entrance of living organisms into the wound."

(If there were putrefactive or septic complications in the wound, the above [as so often since]

Health, Dictionary of Practical Surgery, I and II in one volume. Philadelphia: J. B. Lippincott Co., 1886.

1 to 20 solution is also used for the instruments and sponges during the operation.

I dwell on this point, as there is some difference of opinion as to the use of these 1 to 20 solutions. In order to settle this, I wrote Mr. Lister and received the following reply:

15 PARK CREMANT, PORTLAND PLACE, 11th Dec., 1877

MY DEAR SIR—In reply to your inquiry in your letter of Nov. 26th, received yesterday, I write to say that I use the 1 to 20 carbolic acid lotion for purifying the skin of a part about to be operated on, and also my own hands before I begin to operate, and for cleansing instruments and sponges, and also for the spray when a steam spray producer is employed. The 1 to 4 lotion is our ordinary lotion used for the sponges during the course of an operation, (the sponges having been purified before the commencement of the operation with 1 to 20) and for washing the wound when requisite, and for the lotion in changing dressings. The 1 to 20, I should add, is used for washing (in order to purify them) wounds inflicted accidentally such as compound fractures.

Thanking you for your kind report of the progress which antiseptic surgery is making in America,

I remain, yours very truly
JOSEPH LISTER

A very important feature of this method, is the use of the spray. This is used for the purpose of destroying the septic germs in the air before they reach the wound. So we have to perform our operations and apply our dressings in a cloud of spray formed from a 1 to 20 solution of the acid. The apparatus we generally use is a steam atomizer.

A good spray producer should break up the fluid into a fine cloud, the finer the better as coarse spray soon settles upon the clothing and condenses rapidly upon the bed, and the hands and clothes of the surgeon. The apparatus should be large enough to work for from one and a half to two hours at once. It should be so arranged that it can be placed and maintained at any level that may be desired, and should

Fig. 8.

seems to have been forgotten in Sir Watson's further instructions)

"Disturbance is easily remedied by proper application of a drainage tube. Inflammation of the edges of the wound subsides as soon as the stitches are cut or removed (and more organisms introduced by the dresser' or even by the surgeon himself)

Mr. Cheyne (Sir Watson, later) continued, "The irritation of the antiseptic employed may also interfere with healing. In spite of Lister a earlier emphatic injunctions carbolic acid, carbolized gauze, salicylic acid (powder or ointment) acetate of aluminum, eucalyptus oil, and chloride of mercury (and how many since that time) are all suggested for application directly to the wound surface!

form of wound dressing. The simple dressing employed by my father (John Ashhurst, 2—Pp 16-17 and 22-23) than whom no one secured better wound healing in these preantiseptic days, consisted in lint saturated and kept moist with pure lan-danum, the use of which he had learned from that excellent surgeon Dr Joseph Pancoast after forty-eight hours diluted alcohol was substituted and continued until the wound was nearly healed.

Their objections to Lister's methods were, above all that they were always being changed: first it was carbolic acid then carbolized oil then the carbolic putty then watery solutions then a carbolized cerate plaster then a 'lac plaster' then oil of eucalyptus. Was there to be no end of innovations?

This uncertainty about technical methods in surgical practice has been disturbing ever since. Anxiety about the chemical to be used, the spray material for sutures, dressings and drainage tubes caused surgeons to forget all about "exclusion" of infection, the protection of the wound surface, and the patient.

As one of his house surgeons said, In those days Lister was so sadly misunderstood that the idea became prevalent that he considered carbolic acid possessed a mystical charm over wounds. Only bring carbolic acid upon the scene, and pyæmia and septicæmia would vanish! One day he read to us a letter he had received from a surgeon expressing his disappointment that although carbolic lotion had been sprinkled upon the wound, and basins of it had been placed around the bed, and some had even been sprinkled upon the floor yet the patient died!

Among the controversies that raged about the introduction of the Lister antiseptic method none was more serious or prolonged than that with reference to the use of the carbolic acid spray. Lister himself believed at first implicitly in the importance of this attempt to sterilize the atmosphere. He thought that carbolic acid in the air was just as important as the cleansing of the surgeon's hands or the carbolizing of the dressings by which he hoped to exclude all infection from the wound area.

It is easy as we look back to understand Lister's point of view. Pasteur had performed various experiments with culture fluids in open and closed flasks and flasks with cotton and other kinds of filters to keep out germs. All of these experiments indicated many living organisms constantly present in the atmosphere. Lister felt that any wound surface exposed to an atmosphere so alive with living matter must therefore always be exposed to

the dangers of the putrefaction, fermentation, and infection about which he had been so much concerned.

It was only after a number of years and after becoming convinced of the greater importance in surgery of clean hands and dressings and sterilized instruments that he decided to abandon the spray. The pressure of many colleagues had a good deal to do with this change of mind, but Lister said he was ashamed to have advocated a method which was injurious to the patient, injurious to the operators, and both inefficient and unimportant in protecting the patient against infection.

Since Lister's time it has been shown again that the factors of greatest importance in causing infections in operative wounds or in wounds that are being dressed are the fingers and hands, the dressings and instruments which the surgeon handles, the surgeon's nose and throat, or the poorly prepared skin of the patient himself. These are the sources of most of the primary as well as most of the postoperative mixed infections in these cases.

Even so there occasionally still appear articles about the sterilization of the air by means of chemicals or light or electricity all very spectacular and dramatic but relatively unimportant in the conduct of surgical operations and operating amphitheatres.

A common criticism of Lister's method in the early years and one of the reasons for delay in its acceptance was that Lister declined to collect and tabulate statistical evidence in support of his teachings. As an actual fact, this would not have been difficult to do. Lister himself however was impatient with the statistical method. He realized, as many other surgeons have had to do, that clinical statistics may be accumulated and printed to prove almost anything. Elaborate reports, including statistics with regard to patients, have been manufactured to support theories or points of view without too much care as to their accuracy or even their truth.

As time went by however and after Lister came to Kings' College in London in 1877 some of his own assistants, as well as workers in certain other hospitals, collected and published sufficient material to more than justify the claims that had been made for the antiseptic method.

In 1876, William H. Welch and Frederick S. Dennis finished their services in Bellevue Hospital and went to Great Britain and Europe, for post graduate study. Dennis later became a foremost New York and American surgeon with the somewhat unusual advantage of having always been a first class laboratory man besides. Welch, as everyone knows, was the leading laboratory bacteriolo-

geons the Lister Antiseptic Method for \$100 00 I have heard that when President Grant suffered from the effects of cancer of the throat, Morris wrote to the attending surgeons of New York Philadelphia, and Washington and offered to treat the President by the Lister method if they did not care to do so For these and perhaps other reasons Morris was not too popular in New York Ridlan told the story that at an annual dinner of the American Orthopedic Association at the Knickerbocker Club he sat by William T Bull of New York with Bradford of Boston on the other side Bull said that a few days before Morris had approached him and asked whether it would do his reputation any harm to have a business association with A. M. Phelps one of our early and aggressive orthopedic surgeons of New York Bull said No A day or two later Phelps met Bull and asked whether it would affect his professional standing adversely to be associated with Morris Bull again said No

Morris published several very sound works on the antiseptic method but they inclined too strongly toward a chemical and too frequent dressing sort of listerism His attitude in general is indicated by the following

Mr Lister believed his wounds to be aseptic and the belief has caused greater dispute than its importance warrants for whether or not microbes are present in a wound it is a matter of no importance provided that their growth be so hindered that natural reparative processes are not interfered with (101 p 7)

Morris militant championship of the Lister method reflected more or less the leadership that New York assumed in the use of the antiseptic system in America Partly for that reason perhaps there was some resentment in other parts of this country against the early claims made for the better surgery being done in the New York metropolis.

Although Philadelphia, as upon other occasions, voiced its criticism of the assumptions of New York surgeons, it was demonstrated that there was a basis for the New York claims not only by the final triumph of the antiseptic reform in surgery but by the results being obtained at the time.

C B Penrose in the *Medical News* of October 16 1886 reported upon Antiseptic Surgery in the Pennsylvania Hospital. Commenting upon Penrose article, an editorial writer of the period spoke as follows

New York surgeons have long been accustomed to hear their visitors from Philadelphia after watching the painful and elaborate precautions taken to avoid or overcome infection of a wound declare that they obtained just as good results without such appliances, and that pyemia and

septicaemia were almost unknown in their hospitals.

With the application of strict antiseptics to a limited number of cases, very much better results were at once obtained while the remaining cases treated in the old way (some antiseptic appliances, but no antiseptics) ran the same course as before A list of seventeen major operations conducted aseptically during three months, shows very satisfactory results If a similar condition of affairs exists in any other Philadelphia hospital it is to be hoped that a similar experiment will be promptly tried

There are many passages in the Lister biography by Sir Rickman Godlee that indicate confusion in his mind also as to the true relationship of the original listerian idea to modern antiseptic surgery This is nowhere more in evidence than in his discussion in 1918 of the recently proposed Carrel Dakin method Sir Rickman Godlee said Carrel's treatment would have delighted Lister It is an extension of his own system to infected wounds such as be only attempted or succeeded in carrying out in a limited number of cases, particularly those of operations through parts that were the seat of chronic suppuration

One might feel that Sir Rickman Godlee supposed (in 1918) the Carrel Dakin method to be a real refinement or improvement upon the carbolic washes used by Lister in some of his operations. However it seems quite certain that Lister would have objected to repeated applications of any chemical many times a day to any wound surface. It was always Lister's teaching that chemicals caused irritation and discharge, and delayed healing Also Lister most certainly would have opposed frequent exposure of the wound surface to other kinds of injury by rubber tubes, instruments, gauze dressings, and new infection

Godlee's misapprehension as to the fundamentals of the Lister method show themselves elsewhere in his comments upon the Carrel Dakin method He said

Carrel claims to have solved the problem of the disinfection of wounds, whether the infection be acute or chronic by means of a chemical antiseptic and he calls this treatment "une methode chimiotherapeutique"

It is not strange that Sir Rickman Godlee and others were deceived In the most dogmatic way Carrel laid stress on the following points

The choice of a suitable antiseptic. In the search for such a substance he was helped by Dr

*Carrel, A. and Debelly, G. Le traitement des plaies infectees Paris. Masson et Cie, 97 English translation by Child. London. Bailliere Tindall and Cox, 97

Just as an afterthought—which seems to have deterred no one—he said, Some of these antiseptics are objectionable on account of their poisonous and irritating properties. In the same volume¹ (Vol II p 426) Victor Horsley said regarding the treatment of septicaemia: A vigorous attempt to attack the poison in the system should be made by administering large doses of quinine and salicylate of soda. Ice bags, sponging and “special treatment” (not specified) were recommended for other complications. And that is about where we are now except that we have gone through the sulfa drugs and penicillin to streptomycin. We are beginning to be rational rather than empirical to the extent of better exclusion of infection both during operation and in the postoperative care. We are limiting the inflammatory processes and infectious organisms to wound areas by slowing down the lymph flow with better immobilization and actual rest. And we are now trying to use chemical cures that may not help the patient more but at least hurt him less.

Hey Groves² described in a few words the impasse at which most surgeons had arrived at the turn of the century as follows: “The antiseptic system aims at the destruction of bacteria (by) the action of chemical bactericides. The aseptic system aims at the prevention of wound infection (by) the exclusion of bacteria from the wound (by) heat for the destruction of the germs and using no chemicals in contact with the tissues.”

Hey Groves calls it the modern system to depend upon “vital resistance, exclusion of bacteria, and destruction of bacteria by artificial agencies.”

It seems strange to have this original listerian idea so clearly expressed without going back (in 1911 or now) to 1865 and Lister himself. For that is exactly what Lister proposed with (1) his primary cleansing of skin, instruments, and surgeon's hands with carbolic acid (2) his beeswax carbolic dressing (not in contact with the wound surface) and (3) his care to prevent the access of infection to the wound either by penetration through or around wet dressings.

It should be recalled that Lister had neither the conception of specific pus, gas, or other infections, nor the major role of soiled dressings, instruments, and fingers that we have now.

He was preoccupied with the role of the air as a carrying medium for the causes of wound putrefaction. However his technique was more nearly correct, because of his desire to keep out all germs, than many of our procedures have been since as

¹Health Dictionary of Practical Surgery I and II in one volume. Philadelphia. J. B. Lippincott Co. 1886.
²A Synopsis of Surgery. 5 ed. p 77 New York: Wm Wood & Company. 9

we rely upon mercurochrome, the sulfonamides, or penicillin to compensate made the wound or the patient for sins of commission and omission before, during and after the wound comes under the care of the surgeon.

The drift away from the clinical exclusion of the causes of putrefaction to the laboratory search for a chemical cure for infection, which began with Lister himself and reached its climax in the Carrel-Dakin method had the effect of leading most surgeons entirely away from rest for the wound and the patient, protection of the limb in correct position for compound fractures, and from Lister's own original idea. The wound has been exposed too much and too often in postlisterian practice to permit of an adequate regard for these important surgical principles. The confusing effect of research on fermentation and the effects of chemical antiseptics upon Lister himself however was never as serious as for his followers. Lister after all, kept his original principle of wound protection in mind. Many others who have supposed themselves to be employing the Lister method have not known what the original Lister idea really was.

Even Lister's own pupils and assistants were early led astray as witness the following:

“As regards local treatment under such conditions, it is probably best to go on with the stuffing of the wound with gauze saturated with iodoform or where the wound is extensive or contains sloughs, or where there is a diffuse cellulitis in its neighborhood, it may be advisable to employ constant irrigation with the view of washing away the septic material as soon as it is formed. (31—p. 67).

That Sir Joseph Lister himself was tending in the same direction is shown by his attempt to treat the wound instead of adhering to his original plan of excluding infection. He said:

“The double cyanide might, I believe be very satisfactorily used in military practice as a first dressing by dusting it over the wound with a pepper box, and covering with any absorbent material that might be at hand. The salt might be used with the utmost freedom as experience has shown that there is no risk of its producing poisonous effects. Some surgeons who undertook the use of the cyanide in this way in the late South Africa war had unfortunately no opportunity of doing so at the front. But Mr. Sheatle informed me that granulating wounds behaved more satisfactorily with the cyanide than with iodoform, while the unpleasant odor of the latter was, of course, avoided. (31—p. 48-49)

Robert T. Morris of New York was one of the early enthusiastic antisepticians in America. Reddon told me that Morris advertised to teach sur-

From May 1915 it became evident that wounds treated after a certain method by the aid of hypochlorite or the chloramines of Dakin, were sterilized without any harm resulting to the tissues or the patient. From that date it has been possible to prevent in the greater number of cases infection of wounds, and to abolish almost entirely suppuration in hospitals." (p. 8)

And he commented somewhat sarcastically: Although Sir Almroth Wright's doctrine was founded not on observations and experiments made upon wounds under actual war conditions, but upon ingenious theories and experiments *in vitro* it was accepted by the majority of surgeons. One of them even affirms that asepsis ought to take the place of antiseptics (Hear! Hear! H W O) and that antiseptics not only fail to sterilize the wounds, but that they actually favor the development of microbes." (p. 5)

If one may say wound infection and wound complications instead of microbes Dr Carrel will not only have failed to make the criticism which he intended but will have stated an important truth. A truth moreover which at the very beginning invalidates the premise upon which he undertook to establish the Carrel Dakin method. It is in the ability of the surgeon to anticipate and to assist, or co-operate with the natural forces of the patient in his recovery that he may often be useful at all.

It should be remembered that many of the accidents that occur to surgical patients occur in the course of the efforts on the part of the tissues, or on the part of the patient himself to get well. For example an artery with an ulcerated wall, which may be the source of even fatal hemorrhage, or a large segment of one of the long bones which undergoes necrosis and becomes a sequestrum is an incident in the efforts of the patient to evacuate pus from a cavity which has not been drained early or adequately by his attending surgeon. If this abscess cavity is drained sufficiently early the sloughing of the tissues to provide an avenue for the escape of pus or the involvement of the artery in the ulcerative process may be avoided and the patient may evacuate his suppurating cavity safely. But for his protection the incision must have been made in the right place and at the right time by his surgical attendant. Moreover in the post-operative care the use of mechanical or chemical barriers to prevent the addition of other organisms and the development of symbiosis is equally the opportunity and responsibility of the surgeon who is standing by. Against many accidents to the

wound the patient is as helpless without special help as he is against internal changes that occur within his own structures unless he receives intelligent and prompt assistance from those who have been trained to understand his symptoms to interpret the steps and the progress either of his disease or his recovery and to apply those measures with which the surgeon should have become familiar as a result of our thousands of years of experience.

The surgeon can serve best by protecting the wound surface, the inflamed part and the patient against trauma chemical irritation and infection and by limiting any or all these factors to the original area of injury or operation.

For this we have improved but little upon the rules laid down by Lister and Hugh Owen Thomas. Exclusion of infection and the kind of immobilization that slows down lymphatic flow and limits organisms and toxins to the injured parts is all that the patient usually requires. With reduced amounts of infection and systemic toxemia, he can usually muster the requisite resistance and physiologic defence just as in a simple fracture. At any rate it is to be considered that until we do have specific cures for pus organisms or specific body defenses for wound infections, we should attack less and defend more in the interest of recovery by rest enforced uninterrupted and prolonged.

Annotated Bibliography of Listeriana. All of the items are in the H. Winnert Orr Collection.

Henry D Dakin who after testing a great many fixed upon a solution of hypochlorite of sodium polyborate of sodium, and small quantities of free hypochlorous and boric acids. (Unfortunately Lister himself had led the way in this kind of clinical research.)

The gentle but thorough mechanical preparation of the wound—that is, the opening up of all diverticula, the removal of foreign bodies, blood clots and damaged tissue, and the complete arrest of bleeding.

The introduction of the antiseptic fluid, either by constant irrigation, or at intervals of not more than two hours, through fine India rubber tubes permanently fixed in all the recesses of the wound (Lister said repeatedly not to apply chemicals to the wound surface.)

The daily bacteriological examination of the discharges and the closure of the wound when the number of micro-organisms has been reduced below a number which experience has shown will not interfere with the occurrence of primary union (To undertake the sewing up of any wound containing pockets of organisms is to invite abscesses and systemic infection. There can be no clinical or laboratory test that will tell us when such a sewing up or wound closure is safe. It is a gamble with the patient's limb or life at stake in every case.)

I do not agree with the following statements of Sir Rickman Godlee

Carrel's treatment would have delighted Lister and It is an extension of his own system to infected wounds, such as he only attempted or only succeeded in carrying out, in a limited number of cases, principally those of operations through parts that were the seat of chronic suppuration."

In the War Manual for orthopedic surgery prepared by Brackett and his associates in 1918 (Lee and Febiger) they wisely evaded the confusion regarding antiseptic wound therapy prevalent at that time. No recommendations regarding the treatment of wounds or joint injuries were made at all. Instead the fundamental importance of correct position for injured parts and the orthopedic point of view during both primary treatment and after care was wisely emphasized throughout.

In our orthopedic manual for World War II (Saunders, 1942) the same discretion was not observed. Numerous laboratory and clinical technicians were permitted to exploit their views and certain miracle drugs, to the great detriment not only of immobilization in correct position but even of the exclusion of infection for which Lister had provided us with better standards in 1867. That many were affected unfavorably by the highly toxic sulfa drugs is now also a matter of record.

We continue to disregard the injunctions of Lister and even of many of his contemporaries like Simpson, Tait, Cheyne, and our own Robert T Morris (103). Some of these men were friends and some violent critics of the antiseptic system, but they all recognized the patient and his own defenses as the major ally (not the antiseptics) of the surgeon in surgical care.

Morris said "The patient himself is to be our best ally and in our pride of achievement with artifices against the bacterium, we are not much longer to disregard such an ally as nature gives us in the patient." (103—p. 40.)

"For the last thirty or forty years we have tried so conscientiously and so scientifically to help the patient by following up his bacteria that we no longer past the patient himself altogether" (103—p. 55).

After more than forty years, during which thousands of chemicals and chemical antiseptic methods were tried and after the apparent breakdown of the antiseptic method in the World War I, we arrived at 1916 and the Carrel-Dakin method. The pretended simplicity of curing wound infections by the Carrel Dakin program is indicated by three short quotations with an apparent disregard for everything that had been written upon the subject previously. Dr Carrel said

"On the other hand the problem would appear to be readily solved by using a substance unreacting to the tissues, and of a sufficient bactericidal power to kill all the microbes present in a wound, be their nature what they may.

"When at the end of December 1914, Henry D Dakin and one of the authors of this book (Carrel) sought to discover the best means of treating wound infections, they adopted, for the reasons just stated the method of chemo-therapy.

"The method was applied in the first place to old wounds, afterwards to recent ones. Sterilization was attained in both cases, but the earlier treatment gave more rapid results. It has long been admitted that preventative treatment of a malady costs less in money and toil than a curative treatment. However infection can be checked even after suppuration has become established. In a word, all infected wounds were brought more or less under control by chemo-therapy.

That this program differed in principle in no respect whatever from thousands of similar attempts made between the times of Lister and Carrel does not seem to have occurred to Carrel at all and he claimed 100 per cent control of infected wounds with the same confidence that many others have before and since. Carrel continued

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

HEAD

Bailey H: Parotidectomy: Indications and Results *Brit M J* 1947; 1: 404.

Emphasis is made on the fact that the parotid gland is a bilobed structure consisting of a large superficial, and a small deep lobe connected by an isthmus. The author compares the facial nerve to the meat within the parotid sandwich. It is his avowed purpose to dispel deep rooted misconceptions concerning parotid tumors. These misconceptions are related to the relationship of the facial nerve and the boggy of facial palsy. This has resulted in ill advised recommendations to leave the tumor alone or to wait until it gets larger, it apparently not being realized that as a consequence the seventh nerve will be eventually involved by the tumor anyway and this can be prevented only by surgery. By this time the tumor has become widespread and it is well to remember that the superficial appearance of the tumor now represents its true size. The tumor is likened to a veritable iceberg. It usually arises in a comparatively circumscribed area a little in front of and above the angle of the jaw. The only other common starting point is in the region immediately in front of the tragus. Here the differential diagnosis between an enlarged preauricular lymphatic gland and a mixed parotid tumor is impossible at first, but if the lesion does not subside it is well to consider it a parotid tumor.

True cysts of the parotid are exceedingly rare. The author has seen only 1 case among 100 cases of noninflammatory swellings of the parotid gland. Adenolymphomas, which are cystic tumors probably arising from the lymphoid conglomerate that surrounds the first branchial cleft are definitely benign. Such tumors are exceedingly rare and it is quite impossible to distinguish them from degenerating mixed parotid tumors. Since the operative procedure is less radical for this condition one should take care not to diagnose the condition unless it is bilateral, since an inadequate operation would be done for the neoplastic parotid condition as a consequence.

The author stresses the fact that nearly all parotid tumors are completely radioresistant but despite this fact such therapy is all too frequently recommended to avoid a facial nerve palsy.

He is a strong advocate of subtotal or total parotidectomy rather than enucleation for all cases of mixed parotid tumors. The latter procedure is dangerous because frequently the smaller lesions are merely satellites of the larger lesion. This accounts for the apparently large number of recurrences (30%) in operations performed for small lesions. The author believes that malignant cells spilled during

intracapsular enucleation, or cells left in the interior of a portion of the capsule that has not been entirely removed account for 90 per cent of the recurrences.

It is advocated that a J shaped incision be made beginning at the level of the zygomatic arch, proceeding down the side of the face as close as possible to the pinna and curving around the root of the lobule of the ear to end on the tip of the mastoid process. A large flap of skin is reflected by under cutting. If the whole parotid gland is not in view the incision must be enlarged still farther by extending it down the neck from the tip of the mastoid process, along the anterior border of the sternocleidomastoid muscle. No attempt should be made to remove any parotid tumor until the whole gland is in full view. Only then or even after an extracapsular resection has been begun is it possible to tell how deeply the tumor plunges into the gland. The external carotid artery should be ligated to minimize bleeding. The temporofacial division of the seventh nerve is seen clearly once the superficial lobe has been mobilized. In extracapsular resection sufficient parotid tissue should be removed to ensure that the tumor capsule is not encroached upon. If the tumor is found to extend deeply rather than risk cutting the branches of the facial nerve this operation should be abandoned in favor of superficial lobectomy. The author has done 33 such operations and has noted a salivary fistula in only 1 and this healed within a year.

After operations upon the parotid gland that involve dissection of the seventh nerve and the free use of 60 per cent alcohol in the wound a major degree of facial palsy always occurs and may persist for weeks or months. Early it is well to support the facial musculature by strips of adhesive plaster and, later in cases in which drooping of the mouth persists Dahlberg's internal splint which is a dental prosthesis is best. In 4 cases in which the author had known that he had cut the primary division of the facial nerve, the patients eventually either completely recovered or recovered to such a degree that they are unaware that the nerve is not functioning fully. He believes that the anastomotic twigs connecting the temporofacial and cervicofacial divisions of the seventh nerve, anterior to the parotid isthmus, account for the eventual restitution of function of the seventh nerve when one of its primary divisions is known to have been severed.

In 2 cases the main trunk of the facial nerve was cut and in these instances a strip of fascia was inserted subcutaneously with good effect.

The author fears most the auriculotemporal (Frey's) syndrome following nerve injury in which the patient's cheek becomes red, hot, and painful and beads of perspiration appear upon it when he is

eating. There is also hyperesthesia of the face, especially during shaving.

LEROY J. KLEINSMITH, M.D.

EYE

Bellows, J. G.: Ocular War Injuries. *Am J Ophth* 1947 30 309.

Bellows reports his findings in 300 consecutive cases of ocular war injuries. Although the eyeball measures only 1/375 of the body surface it is frequently injured because of its vulnerability to small particles which might go unnoticed if imbedded in the skin. In each succeeding war there has been an increase in the number of ocular injuries in relation to the injuries to all other parts of the body. Estimates of the eye injuries in World War II vary from approximately 1 per cent of all injuries to from 15 to 17 per cent according to the type of warfare. This series of 300 consecutive patients presented 3 blast injuries, 40 indirect injuries, 299 direct injuries, among which there were 54 nonpenetrating injuries, 206 penetrating injuries and 30 direct injuries to the eye lids, extraocular muscles and orbit and 9 cases of burns of the eyeball and eyelids. 152 cases the injuries were bilateral.

Blast injuries may result from the explosion of shells, grenades or mines. Dust and debris may be driven into the eye by the blast during sudden compression and expansion of the atmosphere. Blast injuries may produce chemosis, hemorrhage causing proptosis and optic atrophy, intraocular hemorrhage following iridodialysis or rupture of a retinal vessel, hemorrhage due to rupture of the choroid and from the retina, and acute iridocyclitis with secondary glaucoma.

Thermal injuries were received by 5 soldiers; they were burns due to fire and burning gasoline. The eyelids were burned and corneal opacities were present.

Indirect injuries result from concussion waves produced by rapidly moving missiles in the vicinity of the eyeball. These injuries more often involve the posterior segment than the anterior because the macular area is the most fragile and vulnerable region. The symptoms and findings vary with the nature of the lesion and may appear immediately or several days or months later. They comprise traumatic hemorrhagic retinitis (hemorrhages, exudates, edema, destruction of arteries and dilatation of veins), paralysis of the orbicularis palpebrarum, exophthalmos, and changes in the vitreous, choroid, retina, and optic nerve.

Direct or contact injuries are produced by the impact of a missile upon the eyeball. Contusion, perforation, penetration, laceration and avulsion may occur.

Nonpenetrating or contusion injuries may reveal corneal abrasions, imbedded foreign bodies in the cornea, conjunctiva, or sclera, or rupture of the eyeball. According to Markelova, 58 per cent of ocular military injuries are nonpenetrating. The following

symptoms and signs may be found: hyphema deep in the anterior chamber, tears of the iris, iridodialysis, rupture of the margin of the pupil, iridodonesis, mydriasis or deformity, dislocation of the lens, cataract and hypotony.

Penetrating injuries generally involve the cornea more than the sclera. One hundred and four cases among 306 in this series required enucleation, 64 eyes retained foreign bodies.

Rupture of the eyeball in 105 cases required primary enucleation or early secondary enucleation.

Intraocular foreign bodies were most frequently found to have entered the eye through the cornea. In war, bilateral involvement is frequent and the particles are smaller, multiple and nonmagnetic or weakly magnetic in contrast to foreign bodies in civilian life. A foreign body within 3 mm. from the center of the cornea is considered anterior to the lens, between 3 and 7 mm. within the lens and between 7 and 24 mm. within the vitreous humor. Copper may produce a purulent reaction or chalcosis bulbi. Aluminum, rock, glass and lead are all tolerated.

The following pathologic lesions were observed in 65 cases: cataract, 30 cases; iris and pupillary lesions, 30; corneal opacities, 18; intraocular hemorrhages, 7; phthisis bulbi, 13; choroiditis, 11; adherent leukoma, 9; retinal detachment, 8; vitreous opacities, 7; endophthalmitis, 4; rupture of the choroid, 3; alderosis bulbi, 3; chalcosis bulbi, 2; hole at the macula, 1 case; avulsion of optic nerve, and sympathetic ophthalmia, 1.

Accurate localization is an important factor in the proper management of intraocular foreign bodies. The Berman metal locator is of value in localizing intraocular foreign bodies, but a negative reaction does not preclude the presence of a magnetic foreign body. The posterior surgical approach was employed in nearly all cases. Among 65 cases of intraocular foreign bodies, 29 magnetic particles were removed in 4 of these cases 2 or more other particles still remained within the eyeball which indicated that magnetic and nonmagnetic foreign bodies are often combined. In 36 eyes the foreign body was considered nonmagnetic.

The results are summarized as follows: in 20 cases enucleation was done, 4 eyes were preserved but blindness resulted; in 22 cases the visual acuity was less than 20/200; in 23, the visual acuity was between 20/200 and 20/40; and in 6 the acuity was 20/30 or better.

JOSEPH ZUCKERMAN, M.D.

BEY, H.: Some Observations on the Symptomatology and Diagnosis of Cases of Proptosis. *Br J Ophth*, 1947 3 55.

The author reviewed his cases of proptosis and classified their origin into three groups. The extra-orbital causes of proptosis were due mainly to the frontal and ethmoidal paranasal sinuses and are usually of an inflammatory nature. Nasal trauma, mucocoeles, pyoceles, and neoplasms were not uncommon causes. Nasopharyngeal tumors, both simple and malignant, occasionally caused propto-

sis. In the intraorbital category the proptosis was found to be due to inflammatory conditions, cysts or new growths. The condition in 23 of the 31 cases in this group was caused by new growths. Proptosis due to disease of the bony wall of the orbit was the least common and was caused by an extensive arteriovenous anastomosis, a capillary angioma and in inflammatory conditions of the orbital wall.

Middle and posterior ethmoiditis may spread into the orbital cavity and produce proptosis but may not present any clinical evidence intranasally. In some of the author's cases x-ray examination in the classical positions proved negative, but repeated x-ray examinations showed the cause to be an ethmoiditis. A comparative x-ray study of both orbits may show an x-ray shadow of a tumor mass or a dilation of one orbit. Shadows produced by soft tissue masses were of two types: the dense and the light. Dense shadows were always diagnostic of an underlying cause of proptosis. Light shadows showed as veiling particularly over the orbital periphery and were always found to correspond to a congestion of edematous orbital tissues and therefore demonstrated only secondary manifestations of the cause of the proptosis. An orbital dilation not due to communication with a sinus has been found to be coincident with the presence of an intra-orbital lesion. This sign was positive in 16 out of 21 cases. The author suggests a therapeutic test in cases of proptosis that could be caused by sinusitis or a gumma. Exploration and biopsy should be resorted to in obscure conditions and biopsy should be done in any case having an appearance of malignancy on exploration, before further surgery is done. Punctures of cysts increase the difficulty of removing the tumor and the possibility of spreading malignant tumors.

ROGER H. JOHNSON M.D.

Zoudek, B. Landau, J., and Bromberg, I. M. Allergy to Endogenous Hormones as a Cause of Keratitis Rosacea. *Brit J Ophth* 1947 31 145.

The authors found that a certain percentage of patients suffering from typical allergic symptoms had a hypersensitivity to their own hormones and it was suggested that this could occur in either men or women independent of their genital function. In general allergic eye conditions are ascribed to hypersensitivity of the ocular tissues to exogenous proteins. However it is also thought that the human eye tissue can be allergic to endogenous products of metabolism, as in sympathetic ophthalmia and phakodanaphylactia where endogenous novel pigment and lens proteins are the exciting agents.

The authors attempt to determine whether or not keratitis rosacea can be caused by the presence in the ocular tissue of an allergy to endogenous hormones. In 6 cases of keratitis rosacea (3 men and 3 women) they tested for the presence of allergy to the various hormones by intracutaneous tests. In all 6 cases they found a hypersensitivity to testosterone alone, and they explained this in women by mentioning that the adrenal tissue also produced testosterone.

All 6 cases had been refractory to accepted methods of treatment and had shown gradual progression of symptoms. In 5 cases the condition was treated by daily subcutaneous injections of small and gradually increasing doses of testosterone and in 3 cases by implantations of testosterone pellets. All patients had a cessation of eye symptoms and an improvement in objective eye findings as well as of the facial rosacea. Keratitis rosacea has frequent spontaneous remissions. Although some recurrences have been experienced in the authors' cases the therapeutic results have been such as to lead them to the conclusion that this treatment is specific.

ROGER H. JOHNSON M.D.

Bárány, E. H. The Influence of Intraocular Pressure on the Rate of Drainage of Aqueous Humor. Stabilization of Intraocular Pressure or of Aqueous Flow. *Brit J Ophth* 1947 31 160.

Duke Elder has proposed a safety valve action theory of aqueous drainage mechanism which postulates that there is no flow of aqueous at normal intraocular pressure but that when this pressure is raised there is drainage of aqueous into the drainage channels. However others have demonstrated a continuous aqueous outflow in man. Since previous methods of measuring the pressure in the drainage channels were done with a cannula under unphysiologic conditions the author has suggested a new method on a completely intact rabbit's eye. Previous experimentation has shown that unilateral closing of the common carotid in rabbits reduced the mean blood pressure in the ophthalmic artery about 30 to 40 mmHg from a normal level of 100 mmHg and the intraocular pressure by about 4 mmHg of mercury from the normal level of about 30 mmHg.

The author injected radioactive sodium isotope Na (24) intraperitoneally and later measured the sodium concentration in the aqueous drawn from both eyes. Carotid occlusion hardly (or not at all) changed the equilibrium concentration of the sodium in the aqueous, and showed that the relative change in aqueous outflow caused by carotid closure must be very nearly equal to the relative change in the rate of entrance of sodium. Calculations further showed that the reduction in rate of entrance of sodium was about 7 per cent, which then very nearly represented the reduction in aqueous outflow caused by carotid occlusion. This result certainly does not support the idea of an overflow mechanism in the intact rabbit's eye. A drop of 10 to 15 per cent in the intraocular pressure should have given a much more pronounced reduction in aqueous outflow if an overflow mechanism had really existed. Therefore there must be some kind of a relative stabilization of rate of aqueous flow. It was assumed that the outflow of aqueous consists of two parts—a hydrostatic part which changes directly with the intraocular pressure and an osmotic factor which is more or less constant. However the blood in the drainage vessel becomes more or less diluted by aqueous humor when it absorbs the efflux

from the anterior chamber which reduces the osmotic attraction along the path of the blood through the vessel. When the intraocular pressure rises more aqueous humor is forced out hydrostatically the dilation will become greater and the colloidal osmotic attraction consequently smaller. When the intraocular pressure falls, the blood in the vessel becomes less diluted and the colloidal osmotic attraction for aqueous rises, which produces a mechanism that tends to maintain a relatively constant flow of aqueous humor in spite of a changing intraocular pressure—the direct opposite of an overall w mechanism. Thus, the osmotic factor in the aqueous outflow mechanism reduces the efficiency of the drainage mechanism in its role of stabilizer of the intraocular pressure. This constant aqueous flow may be a mechanism for protecting the lens. What the situation is in man remains to be seen since man has no trabecular vein. ROBERT H. JOHNSON, M.D.

EAR

House H. P.: Indications for the Fenestration Operation. *Arch Otolaryngol* 94:7 45 3

In selected cases of clinical otosclerosis the fenestration operation has proved of definite value in restoring practical, serviceable hearing.

It is generally accepted that any patient with a bilateral conductive type of hearing impairment who has intact ear drums and patent eustachian tubes and who does not exhibit other obvious pathologic conditions of the ear may be considered as having clinical otosclerosis.

The degree of function of the cochlear nerve is determined by both the tuning fork and audiometric testing. If the patient with clinical otosclerosis has loss of serviceable hearing the duration of bone conduction over air conduction with a 1024 fork is in direct proportion to the degree of cochlear nerve function present. This simple procedure serves as a ready means of confirming the audiometric findings.

Candidates for the fenestration operation may be classified as ideal, borderline and unsuitable according to the amount of nerve function present in the speech frequencies.

Group 1: ideal candidates for fenestration. The members of this group hear the 1024 Muellier magnesium alloy 1024 tuning fork 10 seconds or more longer by bone conduction than by air conduction, and their nerve loss as shown by audiometry is 1 decibels or less for the speech frequencies.

Group 2: borderline candidates for fenestration. The members of this group hear the 1024 fork from 5 to 10 seconds longer by bone conduction than by air conduction. Their nerve loss as shown by audiometry does not exceed 20 decibels for two speech frequencies and is not more than 30 decibels for the remaining 1024 frequency.

Group 3: candidates not suitable for fenestration. The members of this group hear the 1024 fork longer by air conduction than by bone conduction. Their nerve loss as shown by audiometry is more than 30

decibels for two speech frequencies or more than 30 decibels for the remaining 1024 frequency.

If the curve of nerve function continues downward in the frequencies above 1024 the prognosis does not seem as good as it does in the cases in which the curve continues at the same level in the higher frequencies.

A total of 40 patients were classified as of group 1. Of these, 30, or 75 per cent, have maintained practical, serviceable hearing longer than 6 months.

A total of 62 patients were classified as of the borderline group. Of these 34, or 55 per cent, have maintained serviceable hearing longer than 6 months.

Among this series of 112 persons who were observed for more than 6 months after they underwent the fenestration operation for otosclerosis there were no serious complications. Three thought that their hearing was worse after the operation, but audiometric studies revealed both the bone and the air conduction curves to be at the preoperative level.

Six persons belonging to the third group were operated upon with the following results: 3 obtained restoration of practical serviceable hearing, 3 showed an audiometric gain but hearing did not reach the serviceable level, and 1 of them, operated upon for tinnitus obtained relief. JOHN F. DEANE, M.D.

NOSE AND SINUSES

Daley J.: The Role of Columellar and Septocolumellar Sutures in Rhinoplasty. *Arch Otolaryngol* 1947 45 78

Daley states that 90 per cent of all artistic errors in rhinoplasty are centered around the nasal tip, involving the columella, nostrils, septolabial angle and philtrum. He discusses the method of using various columellar and septocolumellar sutures and describes the indications for its use in detail. Sutures should be under as little tension as possible to prevent distortion of the neighboring tissues. The orthopedic suture of Joseph which is used to accomplish elevation of the tip and columella of the nose is most successful when a small bite of the columella not including cartilage is taken. A columella belly suture is recommended to prevent tightening and to keep the columella bowed caudally when the orthopedic suture is used. A ventral septocolumellar suture is recommended to elevate only the tip of the nose for correction of "polly beak." The straight columellar suture is used for closure of the crura of the columella. The perforating suture facilitates implantation of cartilage into the columella through the incision in the membranous septum and permits the cartilage to be maintained in position until manipulations have been completed after which the suture is removed. JOHN R. LEWIS, M.D.

Gatewood W. L.: Substitution of the Chisel for the Saw in Reconstructive Surgery of the Nose. *Plast Reconstr Surg* 9:47 149.

This writer believes that the use of the chisel over that of the saw is of advantage in the operation for

reconstruction of the oversized nose. The advantages are summed up as follows:

- 1 There is definite saving of time and energy
- 2 The severed bone surfaces are left smooth and clear
- 3 There is less trauma to the soft tissues.
- 4 There is no bone dust to produce osteogenesis

A description of the operative procedure is given and 18 drawings are included to illustrate the operation.

WILLIAM A. ARNOX, M.D.

MOUTH

Kanthak, F. F. and Dubrul, E. L.: The Immediate Repair of War Wounds of the Face. *Plast. Reconst. Surg.* 1947 3: 210.

During time of war the problem of immediate or delayed closure of soft tissue wounds assumes greater importance. The authors present their experiences and conclusions reached after the immediate repair of over 450 war wounds of the face. Since gas gangrene and tetanus arising from injuries of the facial structures is virtually unknown it is considered much safer to close wounds of this region immediately. In the early months of the war authorities immediately in their opinions on how to best treat war wounds of the face, but in general the instructions were divided one to debride sparingly to suture skin to mucous membrane where tissue loss existed and not to resect facial wounds early but to allow them to granulate first and then do a secondary repair. The objection to the delayed suture of facial wounds is that in addition to the increased danger of secondary hemorrhage the convalescence of the patient is lengthened and he is not ready for transport so soon as would otherwise be possible. The functional and cosmetic results produced by delayed treatment are not superior to those of primary repair and the discomfort of the patient with a partial loss of a cheek or lip is increased by delay in repair.

The repair of these wounds was done usually within 48 hours after injury. This delay was due to problems in transportation and limited operative facilities. In general, endotracheal anesthesia was used for severe injuries involving the oral or nasal cavities. The bony injuries are repaired first because of the ease of access. Large fragments are extracted, those places having attachment being repositioned, and apparatus is installed on the teeth remaining at this time for fixation of the fractures. Gauze packing is utilized for the thin bones of the middle third of the face to mold them into position. After the bony injuries have been treated the soft tissue is attended to. The margins are trimmed of devitalized tissue, the debridement being extended to an area of good visibility. The mucosa and muscular layers are first closed separately. The mucosa is sutured with interrupted stitches of fine silk, the knots being tied on the oral surface to expedite suture removal. The muscular layer is joined by interrupted stitches of 4-0 chromic catgut or fine silk. It is believed that

closure of the wound in layers is important to produce dispersion of the scar and therefore minimal subsequent contraction of the sutured area. The skin defect is closed with sliding flaps, rotation flaps or interpolated flaps of skin and subcutaneous tissue or more rarely by the use of the free skin graft which serves primarily as a physiologic dressing restricting the full development of contractions. In closure of the skin, the tension is relieved from the cutaneous margins by generous undercutting and by the use of fine white silk or 4-0 plain catgut passed through the deep layers of the skin. The skin itself is sutured either with fine black silk or fine nylon.

Closure of the skin defect by these methods usually places the skin suture line in a different plane than that of the deeper layers in an important protection against contraction of the healing wound in a deformed manner. Whenever possible small inter-polated flaps of skin and subcutaneous tissue are utilized in closure to avoid contracting pulls in straight lines.

All wounds communicating with the oral or respiratory cavities are drained at one or more dependent points by means of rubber tissue. The wound is dressed with a single layer of rubber tissue. The wound is several most dressings to absorb any immediate bloody ooze. Over these are laid a number of gauze dressings and, finally, an elastic cotton bandage is applied over all.

Not over 5 per cent of facial injuries required tracheotomy. Repositioning of the fractured jaws with adequate fixation and the use of adequate pressure dressings to minimize postoperative swelling kept the incidence of respiratory difficulties at a low level. By these procedures the patient is made more comfortable, requires less nursing care, and can be transported earlier than would be possible by delayed treatment.

FRANK F. KANTHAK, M.D.

New G. B. Congenital Cysts of the Tongue the Floor of the Mouth, the Pharynx and the Larynx. *Arch. Otolaryng.* 1947 45: 145

Congenital cysts of the tongue, floor of the mouth, pharynx, and larynx are rare but are particularly interesting because of the difficulty in their diagnosis and the problem of their complete removal. The patient may complain of repeated flare-ups due to infection of some part of the tongue, pharynx or larynx. At the time of such flare-ups due to infection and some fluid may be discharged into the mouth or throat but at the time of the examination nothing can be found to account for the symptoms. One must consider an infected congenital cyst as a possible cause. At times one sees patients who have had such symptoms many years without a diagnosis having been made. Congenital cysts that are not infected may produce no symptoms other than those due to their increase in size.

The term "ranula" has been used to designate a cyst of the anterior part of the floor of the mouth. It should be used only to designate the thin walled

epithelial lined cysts that grow slowly are sometimes of a bluish tinge, and are soft and easily compressible. These cysts fluctuate but do not pit on pressure. They may be present at birth or may appear shortly afterward. They are readily distinguished from a dermoid cyst because of the thinness of their walls. There is no urgency about removal of a ranula unless it is causing difficulty in breathing or eating due to displacement of the tongue. Complete removal of the cyst is the treatment of choice. As the wall of the cyst is very thin, dissection must be carried out very carefully in order to remove all of the lining. The larger cysts may be opened and the lining destroyed by superficial surgical diathermy.

A cystic hygroma is a multilocular lymph cyst which usually occurs primarily in the neck but may involve the floor of the mouth. A cystic hygroma usually is found in the floor of the mouth or in the submental or submaxillary region. These cysts are multilocular lymph cysts. They have thin walls and an endothelial lining they usually are filled with clear lymph. They are retention cysts due to obstruction or lack of development of the afferent lymph vessels. Examination discloses a smooth thin cyst in the floor of the mouth, which causes bulging of the tongue. Palpation of the neck reveals an enlargement on one or both sides. Surgical removal is satisfactory if the patient can stand the operation. At the Mayo Clinic, however they have treated nearly all of these cysts with external irradiation or radon seeds.

A dermoid cyst which involves the floor of the mouth and the submental and submaxillary regions may be situated either above or below the mylohyoid muscle, or may extend from one region to the other through the muscle. The large cysts cause bulging of the floor of the mouth. The tongue may be back against the pharynx and may not be visible. The submental region may be filled out like a large orange. They may occur in infants and interfere with feeding and deglutition. In the differential diagnosis of the dermoid cysts, one must think of enlargement of the sublingual or submaxillary glands and of a salivary calculus. Complete removal of a dermoid cyst is advisable and the approach should be made either externally or through the floor of the mouth, according to the location of the largest part of the cyst. If the cyst is to be removed through the floor of the mouth, an incision is made over the tumor and, after the wall is exposed and a line of cleavage is established, the cyst may be removed by blunt or finger dissection. Even cysts which have extended submentally may be pulled up through the muscle and removed through the mouth. Cysts that are situated in the submental region and have not extended very far into the floor of the mouth or are badly infected are best removed externally through a submental incision.

Aberrant thyroglossal cysts may cause repeated inflammatory swelling of the base of the tongue if they become infected. If a portion of the cyst remains below the hyoid bone, it produces swelling

in the neck or a thyroglossal sinus externally in the midline. If there is incomplete obliteration of a thyroglossal duct and a portion remains in the region of the foramen cecum, repeated infection may cause a great deal of trouble. The treatment of this lesion consists of removal of the cyst or cystic tract in the interval between infections.

Branchial cysts may be present laterally in the pharynx in the region of the posterior pillar, or below the tonsil or in the hypopharynx and at the base of the tongue. The opening of the branchial cysts may be enlarged under suspension laryngoscopy and the cystic tract destroyed by surgical diathermy with a protected point. A congenital cyst of the larynx or a branchial cyst which extends laterally in the region of the vallecula may be removed under suspension laryngoscopy by surgical diathermy.

Congenital cysts of the larynx may not produce symptoms until adult life or may cause death because of laryngeal obstruction by the mass present at the base of the epiglottis and side of the larynx. Lateral thyrotomy, division of the thyroid cartilage and dissection of the cyst with a cotton applicator without exposing the larynx itself has proved to be a very satisfactory operation for complete removal of these cysts.

Sharp, G. S., and Spickerman, H. D.: Cancer of the Tongue. *Am J Roentg* 947: 57, 8.

The authors report 5 year cures in 31.3 per cent of 8 cases of carcinoma of the tongue treated by roentgen therapy combined with interstitial radium therapy. Excessive smoking and dental trauma to the tongue were considered common etiologic factors. Lingual carcinoma was found to metastasize and infiltrate early. Immediate biopsy and histologic irradiation was considered important.

The number of 5 year cures was found to vary with the location, decreasing progressively in the following order: tip, borders, dorsum, and base. The more adult type of epitheliomas occurred at the tip, and the anaplastic, high grade, embryonal cell type occurred at the base. Over 90 per cent of all the cases were epidermoid carcinomas.

The authors believed that dissemination of carcinoma cells due to infection was prevented by treatment with penicillin and sulfa drugs. The primary lesion was treated exclusively by irradiation combining x ray therapy with the subsequent implantation of radium needles. Whenever possible roentgen therapy was given through the mouth, however for lesions at the base of the tongue supplementary external radiation was necessary. By using a short target-skin distance the total dose of roentgen therapy given by the method described varied from 4,000 to 4,800 roentgens given in from 10 to 12 days. Subsequent radium needle therapy was given in the average total dose of 100 mgm. hr. to the anterior two-thirds of the tongue and of 800 mgm. hr. to the base of the tongue. Soft tissue breakdown and osteonecrosis was minimized by this method.

JOHN R. LINDVAT, M.D.

Klein D: Classification of Maxillofacial Injuries Plast. Reconstr. Surg. 1947 : 133

The author reviews a series of cases of maxillofacial injuries admitted to an evacuation hospital. A plan of care was evolved in which evaluation of the injuries and classification of the varying degrees of such injuries were made. This plan made possible more accurate diagnosis and a better approach to treatment and prognosis. The application of these findings to civilian practice has been noted by the author.

Because of the wide variation in the extent of the injuries and problems involved in caring for the patients group classifications were made.

- Group 1 Primary maxillofacial injuries
 - (a) Without hemorrhage or obstruction
 - (b) With (1) hemorrhage (2) obstruction
 - (c) or (3) both
- Group 2 Maxillofacial injuries with concomitant wounds

The patients in group 1 a were usually comfortable with little need of sedation and they exhibited few if any signs of clinical shock regardless of the severity of the injuries. Extensive primary repairs were well tolerated.

The patients in group 1 b suffered in addition from noticeable loss of blood respiratory obstruction, or both they were acutely ill and presented many manifestations of clinical shock.

Treatment was directed to replacement of the lost blood and the establishment of an adequate airway. When these criteria were met, primary reparative surgery of any degree was carried out as in the first group.

In Group 2 with facial injuries and concomitant cerebral, thoracic abdominal or extremity injury treatment of the facial injuries was carried out currently with that of the other injuries in the belief that recovery was not compromised and minimal scarring and deformity were the result. The principles of immediate reparative surgery or early repair were adhered to and emphasized, and particular attention was paid to patients developing unexpected signs and symptoms. Concealed injuries were suspected in these cases.

Excellent case histories illustrate the course and treatment of the cases in each classification the medical surgical and mechanical data are complete.

FREDERICK W. MERRIFIELD M.D. D.D.S.

PHARYNX

Révész, G: The Role of Mechanical and Anatomical Factors in the Problem of Tonsillar Foci.
J. La. Med. Assoc. 1946 61: 390.

Révész believes that the anatomical location of the palatine tonsil between the superior constrictor laterally palatoglossus anterior palatopharyngeus posteriorly and tongue inferiorly renders it susceptible to pressure or massage during swallowing. He found on experimentation that radiopaque material was more slowly expressed from the crypts of deep

scated tonsils during deglutition. From this observation he reasons that the products of bacterial action when present are expressed into the oral cavity from superficially situated tonsils but toward the capsule from those deeply seated. The central pressure tension exerted by these muscles mainly those in the pillars is calculated to be about 0.45 kgm/cm². These findings are advanced in support of his contention that improvement is more frequent following the removal of deep seated tonsils when one is seeking to eliminate foci of infection.

JOHN R. LINDAY M.D.

Figl F A. Cicatricial Stenosis of the Nasopharynx; Correction by Means of a Skin Graft. Plast. Reconstr. Surg. 1947 : 97

Thirty-seven cases of cicatricial stenosis of the nasopharynx have been encountered at the Mayo Clinic. Many authors have stated that syphilis is the most common cause of cicatricial stenosis of the nasopharynx. This is decidedly in contrast to the findings in the cases observed by the author. Excessive trauma inflicted during tonsillectomy alone or combined with adenoidectomy induced the stenosis in 30 (54 per cent) of the 37 cases. Syphilis was causative in 8 (21 per cent) cases an indeterminate inflammatory process in 3 rhinoscleroma in 2 a lupus in 1 and an attempt at surgical correction of a congenital malformation of the throat in 1. The duration of the stenosis at the time these patients came for consideration varied greatly. Narrowing of the nasopharynx in these cases may range from slight asymptomatic contracture to complete closure. The symptoms of stenosis of the nasopharynx are essentially those of accessory anuses and commonly are referred to the nasal obstruction and to the ears. They are dependent to a great extent on the degree of stenosis. Attempts have been made to reline the nasopharyngeal lumen by means of a skin graft but usually these have failed because the graft was inadequately immobilized.

In the following case an acrylic obturator was used and an excellent result was secured.

The patient a housewife aged 50 years came to the clinic for treatment on September 16 1946 because of nasal obstruction of 11 years duration. She had undergone tonsillectomy in 1932 and the wound had failed to heal. At that time results of serologic tests for syphilis were positive.

Examination of the patient at the clinic revealed dense cicatricial atresia of the nasopharynx complete destruction of the uvula, and extensive scarring of the entire posterior and lateral walls of the pharynx. No other clinical signs of syphilis were observed. On serologic examination reaction to the Kahn test was doubtful, results of the Hinton and Kolmer tests were negative, and results of the Hinton and Kolmer tests were negative, and examination of the cerebrospinal fluid gave completely negative results.

Antisyphilitic treatment with penicillin was begun and 5 days later surgical correction of the atresia of

the nasopharynx was undertaken. Local anesthesia was used. The tip of a heavy curved probe inserted through either nostril into the nasopharynx was barely palpable through the densely scarred palate but it was possible, by use of the probe, to determine the approximate level of the reflection of the mucous membrane on the posterior wall of the nasopharynx and the superior surface of the soft palate. A transverse incision, approximately 4 cm. in length was made across the posterior wall of the pharynx below the lower border of the scarred attachment of the soft palate to the posterior wall of the oropharynx. This was carried entirely through the thickness of the scarring and was then extended upward in order to free the palate widely from its attachment to the posterior pharyngeal wall. The opening thus created was enlarged sufficiently to permit insertion of the index finger through it into both choanae. A sponge rubber mold through which two rubber tubes had been inserted for nasal breathing was then covered with a split-skin graft of medium thickness. The graft had previously been taken from the anterior abdominal wall. This graft was drawn up into the restored nasopharyngeal lumen by means of two heavy silk ligatures attached to its upper surface and brought out through the nostrils. Although the sponge rubber mold was of such size and shape as to be self retaining supplementary anchorage was deemed advisable and was secured by tying together the traction ligatures mentioned previously, below the columella over a small rubber tube. In addition the edge of the palate and the pharyngeal incision were sutured directly to the skin graft and the mold supporting it.

Treatment with penicillin was continued postoperatively and the patient's convalescence was uneventful. The mold was removed for inspection of the graft on the tenth day. Complete take of the graft had been obtained. At the end of two weeks the sponge rubber mold was replaced with a self retaining acrylic obturator and the patient was dismissed from the hospital. The obturator was taken out for cleansing on alternate days and was worn for approximately 2 weeks.

The patient was dismissed from the clinic on the thirty third postoperative day. At that time the nasopharyngeal lumen measured approximately 1.5 cm. and had shown no tendency to contract since removal of the obturator a week previously.

NECK

Robertson, J. D.: Thyrotoxicosis as a Surgical Problem. *Brit. J. Surg.* 46: 34. 94.

The author presents a review of the literature and of his personal experience with iodine in the pre- and postoperative care of patients with hyperthyroidism. His work is divided into three sections, namely:

1. Iodine and iodide dosage in thyrotoxicosis, and its effect on the basal metabolism as a guide to operation. The preoperative use of iodine reduced the operative mortality for thyroidectomy in thyrotoxicosis

to less than 1 per cent. The mechanism of action of iodine on the hyperplastic thyroid is obscure, but it seems clear that iodide, free iodine, tincture of iodine, a strong solution of iodine (Lugol's solution), and calcium iodobenzoate are equally effective or the basis of total iodine, and that approximately 200 mgm. of iodine should be administered daily (by mouth). The common practice of giving iodine routinely for 10 days before operation is not approved by the author who showed that the basal metabolic rate often remains high for longer than 10 days after instituting iodine administration: some patients become refractory to iodine and the metabolic rate rises then, in spite of iodine administration. In such cases iodine should be withheld for several weeks then, usually on starting iodine therapy again, the metabolic rate falls to normal. Usually the pulse rate changes parallel those of the basal metabolic rate. Robertson states that the basal metabolic rate is the best guide for choosing the time for surgery.

2. The postoperative reaction after subtotal thyroidectomy for the relief of thyrotoxicosis. There is almost always an elevation of temperature for 1 or 2 days after thyroidectomy. That this is due to surgical trauma, and not to the liberation of thyroid hormone or any toxic substance specific to toxic goiter is shown by the fact that the same degree of temperature increase occurs after removal of nontoxic adenomas, of secondary glands of the neck, or of a chronically inflamed appendix. Blood pressure changes are also shown to be the same for different types of operation, and are not due to the type of anesthetic used.

3. The effects of iodine medication after subtotal thyroidectomy for thyrotoxicosis. Opinion varies concerning the value of iodine administration after thyroidectomy. The author compared a group of patients who received iodine both before and following operation with a group of patients who received iodine only preoperatively. On the average the preoperative basal metabolism of the second group (no postoperative iodine) was higher but normal metabolism was reached at about the same time postoperatively by both groups. Robertson therefore concludes that there is no value in the administration of iodine after subtotal thyroidectomy for hyperthyroidism. Finally he states that if iodine is not continued after subtotal thyroidectomy it is possible to state by the twelfth day after operation whether the thyrotoxicosis has been relieved. If the basal metabolism on the twelfth day after operation is higher than the lowest preoperative level or above normal limits, then the thyrotoxicosis has not been relieved. The basal metabolism is a more sensitive index of an unsuccessful operation for the relief of thyrotoxicosis than the pulse rate, the weight, or the clinical symptoms.

CLEGG, H. THOMAS, M.D.

Raveno, W. S. Propylthiouracil in Thyrotoxicosis. *J. Am. M. Ass.* 947 33 190.

The author reports his observations on 54 patients with thyrotoxicosis, who were treated with propyl-

thiouracil, a thiouracil derivative. The antithyroid action of propylthiouracil in rats is approximately ten times that of thiouracil, and while it is more toxic than the latter on a weight basis it is less toxic in quantities having a comparable therapeutic effect.

Clinical observations on the first 54 patients treated with propylthiouracil indicated that 30 to 75 mgm. and 15 to 50 mgm. a day is an adequate initial dose. The antithyroid action is less intense than that of thiouracil, myxedema and thyroid enlargement have occurred only infrequently, and side reactions not at all. This study gives the impression that propylthiouracil has about five times the activity of thiouracil with few if any of the disadvantages present of the latter.

Of the 54 patients treated with propylthiouracil during a period of 4 months, 18 had not received previous treatment. Of these 18 patients 13 had toxic nodular goiter and 5 had toxic diffuse goiter. Thirty-seven patients still on varying maintenance doses of thiouracil were given the new agent instead. Of these 13 had toxic nodular goiter and 14 had toxic diffuse goiter. Five patients who were unable to take thiouracil because of drug fever or urticaria were also included in this study.

In the group of 10 previously untreated patients with thyrotoxicosis, 10 responded with an abatement of symptoms, gain in weight and a return of the metabolic rate to normal within 4 weeks on the basal dose of propylthiouracil ranging from 50 to 75 mgm. a day. One patient responded after 21 weeks treatment and in 1 other patient responded after a period of 41 days. Five patients showed varying degrees of response, just short of complete control because of too low dosage.

Thirty-six patients on maintenance doses of thiouracil were given propylthiouracil instead. The disease in 13 patients continued under satisfactory control while that of 13 was not controlled as well again because of too low dosage. Apparently it takes at least 33 mgm. of propylthiouracil to match the effect of 100 mgm. of thiouracil, which would make the potency of propylthiouracil three times that of thiouracil. An effective initial dose comparable to 100 mgm. of thiouracil should accordingly be 300 mgm. of propylthiouracil daily.

In 2 patients typical drug fever developed with propylthiouracil but no other toxic reactions appeared. The five patients who had developed with thiouracil but no other toxic reactions appeared because of toxic reactions tolerated propylthiouracil without toxic reactions.

Evidence of a toxic effect on the blood, or the blood-forming tissues has not been noted in the present series of patients. Blood counts were performed every week at first then every 2 to 4 weeks. In no instance was there leukopenia, granulocytopenia, or anemia.

Propylthiouracil is a potent antithyroid agent fully as effective and much safer than thiouracil, although it too is capable of producing a toxic reaction, as has been demonstrated. JOHN H. MORGAN M.D.

Hinsworth, H. P., Morgans, M. E., and Trotter, W. R.: *Thyroidectomy and Thiouracil in Toxic Goiter: An Interim Comparison*. *Lancet* London 1947; 1: 241.

Subtotal thyroidectomy may be performed on the thyrotoxic patient as soon as he shows sufficient improvement in his condition from thiouracil therapy.

Ninety-one cases of toxic goiter were treated with thiouracil or methyl thiouracil. In 12 cases operation was decided upon at the initial examination. In these cases thiouracil was used solely to prepare the patient for the operation. In another 13 cases the drug had to be discontinued because of toxic effects and 1 other patient died of a coronary thrombosis during treatment.

A total of 65 cases of toxic goiter were treated with the thiouracil drugs. These cases were compared with a similar series of 93 cases treated by subtotal thyroidectomy. The pulse rate and basal metabolic rate both showed reduction during the first 3 weeks and there was a great similarity in this reduction due to both subtotal thyroidectomy and thiouracil. There was no appreciable difference in the condition of the patients treated with thiouracil and of those treated by subtotal thyroidectomy.

The authors state that the mortality from subtotal thyroidectomy is less than the overall mortality from thyroidectomy. They state, however, that thyroidectomy is advisable when tracheal obstruction is present when a drug reaction occurs and when the patient is unable or unwilling to attend regularly for review for an indefinite period.

Of 25 patients in whom the administration of thiouracil was stopped, 7 had a relapse but there was no relapse in 13 who had been under treatment for a year or longer. In the group as a whole, the longer patients were followed after the cessation of treatment the more frequently did relapse occur.

REINOLD J. BENNETT JR., M.D.

Vander Laan, W. P., and Swenson O.: *The Results of Surgical Treatment in Graves Disease*. *A. English J. M.*, 1947; 235-236.

In view of the many discussions regarding the relative merits of medical and surgical therapy in the treatment of hyperthyroidism, the authors have studied 149 cases surgically treated at the Peter Bent Brigham Hospital in Boston, Massachusetts from 1923 to 1940. Nineteen patients whose conditions were satisfactory at discharge failed to report back to the clinic therefore, the analysis pertains to 130 months.

Eighteen patients were studied for a minimum of 6 months. Nine suffered only mild hypothyroidism, and 7 had classic signs of myxedema. Of the latter 7 had metabolic rates ranging from 31 to 47 per cent. All 18 were given thyroid with satisfactory results.

Seven patients had unilateral vocal cord paralysis immediately after surgery. In 1 case it occurred after a hemithyroidectomy and the patient refused

the second stage of the operation. The 6 other patients suffered only a temporary paralysis.

Four patients showed hypoparathyroidism. In 3 there was evidence of permanent parathyropria. Tetany was produced preoperatively by hyperventilation. It was symptomatically controlled with vitamin D. Symptoms disappeared spontaneously after a few months in the 3 other patients.

Thirteen patients showed persistent exophthalmos. The Naessiger operation was performed on who showed a progression of exophthalmos. Of the remaining 18 patients, 3 showed marked exophthalmos.

Six patients had a recurrent thyrotoxicosis from 8 months to 4 years after surgery. Two were successfully treated with iodine. Two were reoperated upon; in 1 the result was successful but the other patient failed to return to the clinic. The remaining 3 cases were not studied.

Five patients had a persistence of the disease after surgery. Two were sent to radiologists. Two could not be followed up. The fifth patient was operated upon 3 times and made a complete recovery after the third operation.

Four patients died as a result of surgery. Two had a postoperative thyroid crisis and 1 had hemorrhage into the wound with cessation of respiration. The fourth fatality occurred in a woman who refused further treatment after a response to iodine. She continued taking iodine for 10 months after discharge. She was readmitted and iodine was withheld for 3 weeks. When it was again administered, she failed to respond. She died on the operating table.

One hundred and thirty patients were followed up for more than 6 months. One hundred and thirteen patients, or 87 per cent, had a satisfactory outcome. 17 or 13 per cent had either recurrence, persistence, parathyropria, vocal cord paralysis, and some died all of the results being considered unsatisfactory.

DANIEL REGEZ, M.D.

Puppel, I. D., LeBlond, C. P., and Curtis, G. M.: The Surgical Therapeutic Significance of the Functional Behavior of Thyroid Nodules. *Ann. Surg.* 947: 5-57.

The quantitative relations of thyroxine iodine, diiodotyrosine iodine, and inorganic iodine of excised thyroid tissue were determined, both for radioactive iodine and ordinary iodine.

The tissues were obtained at operation on 7 patients. There were 3 cases of nontoxic diffuse colloid goiter, one of which also exhibited a fetal adenoma, 3 cases of nontoxic nodular goiter, 1 case of exophthalmic goiter with 3 small colloid nodules, 1 case of nodular goiter with mild hypothyroidism, and 1 case of mildly toxic nodular goiter. In all of these the nodules exhibited a similar reaction to ordinary and radioactive iodine: the nodules showed less uptake of iodine than the surrounding thyroid tissue and manufactured less thyroxine and diiodotyrosine from the administered iodine than did the parathyroid thyroid tissue. Diffuse colloid thyroid tissue showed considerable avidity for administered iodine but

not much increase in production of thyroxine and diiodotyrosine. Diffuse hyperplastic tissue of exophthalmic goiter exhibited the greatest avidity for iodine and the greatest ability to produce thyroxine and diiodotyrosine. The question was raised as to whether the toxic manifestations in toxic nodular goiter are due to the nodules or to the parathyroid tissue.

CLARENCE H. TRENCH, M.D.

Outerbridge, R. E.: Malignant Adenoma of the Thyroid, with Secondary Metastases to Bone. *Ann. Surg.* 947: 125-132.

The present report is concerned chiefly with 5 cases of malignant adenoma of the thyroid with metastases to bone, seen at the Toronto General Hospital (Canada). In the last 50 years, 1,768 thyroidectomies were performed at this hospital. Sixty (3.4%) were done for carcinoma of the thyroid. Of these, 21 were diagnosed as adenocarcinoma or malignant adenoma of the thyroid. The 5 cases referred to presented similar metastases to bone: the symptoms first directing attention to the secondary tumor rather than to the lesion in the thyroid, and biopsy of the tumor showed that it was composed histologically of apparently quite benign thyroid tissue.

Case 1: A male, aged 49, had an 18 months history of a hard, painless lump the size of an olive in front of the right ear. This increased in size, and on admission he had a large pulsatile swelling, the size of half an egg, involving the right axilla, a smaller mass involving the fifth rib in the anterior axillary line, and a third pulsating mass over the second lumbar vertebra. A small nodule the size of a bean was felt in the right lobe of the thyroid. There was no evidence of hyperthyroidism.

Biopsy of the tumor in the right axilla proved it to be an extremely cellular mass, which reproduced fairly typical thyroid acini filled with colloid material in some sections. Other sections revealed colloid cells growing in small compact pseudocystic arrangement and in cylindrical cords. There was blood vessel invasion as well as atypical characteristics of the cells.

A right thyroid lobectomy was done, the lobe contained two nodules, (the left thyroid did not appear to be involved). The nodules presented the same characteristics as the metastases. Deep roentgen therapy was begun 1 month after admission, and 9 months later the patient presented metastases in the first and fourth lumbar vertebrae, the left pubic bone, and right wing of the ilium. Approximately two years later he was admitted because of large metastasis involving his left femur. He subsequently developed a spastic paraplegia and cord trouble. He died just 5 years after the onset of his trouble. Post mortem examination presented rather widespread metastases by more or less discrete growths which had shown little tendency to invasion of the surrounding tissues.

Case 2: A female, aged 73, entered the hospital with the history of a tumor of eight months duration and of increasing size in the left parietal region.

On admission the tumor was found to be a firm, painless nodule the size of a walnut lying deep to the skin and attached to the bone. The roentgenogram showed a punched out decalcified area about 1.5 cm in diameter. Her thyroid contained two small, firm painless nodules. The tumor of the skull was removed with the surrounding bone, and on microscopic examination revealed typical benign thyroid tissue.

Case 3. A female aged 41 was admitted with a 3 year history of occasional pain down the right forearm and wrist, noted chiefly on movements of supination. One and one half years before admission she had struck her right forearm, and following this she noticed the gradual development of a lump. On admission there was a firm, pulsating slightly tender mass the size of an orange involving the upper and outer aspect of the right forearm. X-ray films showed involvement of the upper one-quarter of the right radius, with the exception of the head and one half inch of the neck. There was complete destruction of the shaft of the bone leaving normal bone at each end. Biopsy revealed connected cords of acidophilic cells grouped in alveolar formation and containing colloid a typical picture of benign metastasizing tissue.

There was no evidence of hyperthyroidism, but there were two small palpable nodules in the right lobe of the thyroid gland. A subtotal thyroidectomy was done at which time two adenomatous masses were found, one benign and the other malignant. Following this, the tumor of the radius was resected.

Case 4. A female aged 67 was admitted with a history that following a fall 4 years previously she noticed the gradual onset of weakness and numbness of both legs. On admission she had complete loss of motor power of both legs and loss of pain touch, and sense of vibration below the xiphisternum level, and urinary retention. Roentgenograms revealed a tumor involving the fifth thoracic vertebra and the proximal portion of the posterior end of the fifth left rib. Laminectomy revealed a vascular tumor which, on microscopic examination revealed thyroid tissue of benign appearance.

The right lobe of the thyroid was enlarged. The patient was given a total of 4 courses of deep roentgen therapy to the thyroid gland and to the area of the fifth thoracic spine in the following year. There appeared to be no change in the thyroid but the neurologic status was improved.

Case 5. A female aged 30, was admitted with a history of adolescent goiter at the age of 12. There was no increase in size until recently. A thyroidectomy was done because of pressure symptoms and examination of the tissue demonstrated malignancy with invasion of blood vessels. Two months later the patient noted increasing weakness and numbness of both lower limbs and examination showed an incomplete spastic paraplegia, paresthesia and some sensory loss involving the lower portion of her trunk and lower limbs. Radiologic examination showed bone destruction of the seventh cervical and first tho-

racic vertebrae and spinal puncture demonstrated complete block in this region. A cervical laminectomy was done and since the lesion was so extensive only a biopsy was possible. This revealed a typical benign type of thyroid tissue. The patient was given a total of five series of telerradium to the region of the cervicodorsal spine. Gradual improvement resulted.

These cases illustrate the main features of the condition. Usually the patient first comes to the hospital because of symptoms produced by the bony tumors. Despite the benign appearance of the histopathology of these metastases a malignant primary focus can always be found in the thyroid gland. This primary process is usually a well encapsulated adenoma which has become malignant. In the present series only 33 per cent of malignant adenomas had formed metastases by the time the primary growth was removed from the thyroid gland. Metastases from this type of tumor have a predisposition for the osseous system. The metastatic tumors have a tendency to invade bone by growing in an expansible manner and eroding the bony cortex and the roentgenogram is suggestive of an osteolytic sarcoma or giant cell tumor. These bony metastases are frequently pulsatile and occasionally enlarge during menstruation and pregnancy.

Complete excision of the primary malignant adenoma and metastases would seem to be the most rapid and effective means of dealing with this problem. The effectiveness of this means of treatment depends on removal of both primary and secondary growths early and the slow growth of this tumor is in the surgeon's favor. His cases suggest that a period of at least a year elapses after the formation of the first metastatic tumor before others begin to develop. Deep roentgen therapy seems to have found a definite place in the treatment of this condition.

A plea is made for the recognition of the gravity of these lesions which should be reflected by early complete and adequate treatment.

LaROY J. KLEINBAUER, M.D.

DeMoraes Grey J. A Study of Thyroglossal Vestigial Tissues (Conduita em face dos "vestigios" tireoglossais). *Rev. Brasil. Cir.* 1947 16 31.

Aberrant goiter should be distinguished from so-called accessory supernumerary or remanent goiter, the latter being confined to the triangle formed by the lower jaw and both carotid arteries. The author reports 4 cases of cysts and fistulas in the last mentioned region.

Accessory goiters must be considered as vestigial formations in the region of the thyroglossal canal. They may be divided into upper or glossohyoid and lower or thyrohyoid groups. The fistulous tract may lie behind or in front of the hyoid bone or it may pierce it. A cure can be obtained only by complete excision of the tract. To facilitate the dissection the hyoid bone should be resected. When the dissection is finished the remaining portions of the hyoid bone are sutured with catgut. Injection of

methylene blue facilitates the visualization of the tract.

The operation can be performed under local anesthesia except in cases in which the goiter is located at the base of the tongue, when a general anesthesia with intratracheal intubation is preferable. Muscle tissue, aponeurosis and hyoid bone must be sacrificed to accomplish complete excision of the tract. While resecting the hyoid bone care should be taken to avoid the external carotid artery.

JOSEPH K. NARAY, M.D.

Lenz, M.: Cancer of the Larynx. *J Am M Ass* 947:134:17

Of 110 patients who received roentgen therapy for carcinoma of the larynx during the period from 1931 to 1941, 27 per cent were free from clinical evidence of cancer for 5 to 14 years. The remaining 73 per cent were not cured; either cancer persisted, or radiation edema, radionecrosis or metastases were present at death.

The principal factors influencing prognosis are (1) the local extent to which the larynx has been involved and (2) metastasis to the lymph nodes. When invasion of the arytenoid cartilage is incomplete or there is no fixation, 50 per cent cures (for 5 to 14 years) are obtained; when there is complete fixation only 12 per cent of the patients are free of cancer for periods of from 5 to 14 years. Among patients without clinically demonstrable metastatic lymph nodes, 33 per cent are cancer free after periods of from 5 to 14 years. Among those with metastasis when first seen, only 15 per cent are cancer free.

The microscopic classification of the cancer is of only slight prognostic significance since 37 per cent of both the well differentiated and the undifferentiated cancers are the group of patients who are

cancer free after from 5 to 14 years following roentgen treatment, while only 26 per cent of the moderately differentiated cancers are among the patients who remained cured after periods of 5 to 14 years.

Since the results following roentgen therapy in early cordal cancer compare favorably with those following laryngofissure and cordectomy and roentgen therapy results in a much better voice than can be obtained with treatment by laryngofissure, roentgen therapy is recommended as the treatment of choice in early laryngeal cancer. Laryngectomy is the treatment of choice if there is complete fixation of the arytenoid cartilages. In cases of partial fixation the author believes that a full course of roentgen therapy should be given and the decision for laryngectomy deferred for a period of about 3 months to determine if the treatment has eradicated the disease.

The usefulness of prophylactic postoperative roentgen therapy after laryngectomy is questionable. Radical neck dissection is advised if there are movable clinically involved nodes, whether few or many. When any lymph nodes are fixed, irradiation (roentgen or interstitial) is recommended.

Roentgen therapy is also recommended for cancer of the epiglottis, ventricular band, and anterior parts of the aryepiglottic folds even after fixation of the arytenoids and lymph node metastases. Cancer of the piriform sinus responds poorly to roentgen therapy.

A modified Coutard technique is employed, with a reduced daily dose and irradiated area to conserve normal tissue resistance. An average dose of 5,700 to 7,000 roentgens is given at the rate of 100 roentgens to each side daily over a period of 5 or 6 weeks, through as small a field as possible, usually 6 by 3 cm. or smaller when possible.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Friedland, F. and Margolin, R. J.: *Physical Rehabilitation of Patients with Brain Injuries*. *Occup Ther Rehabil* 1947 26 8.

The authors have had experience with over 80 patients at the Cushing General Hospital. All of the patients were suffering with major brain injuries which had produced varying degrees of the cerebral type of paralysis as well as mental changes in some instances. It became obvious to the authors early in their work that the conventional forms of heat massage and passive exercise were alone not sufficiently effective to rehabilitate this difficult and entirely worthy group of patients. They found that it was necessary to teach posture, balance, co-ordination, and eventually ambulation, by special training which included re-education of all the muscles of the body.

The condition of some patients was such that individual attention was necessary; the treatments particularly beneficial to the special patient being administered by trained attendants. Gymnastics classes including group exercises and games, constituted the other major portion of the rehabilitation program. In all training, not only was an attempt made to regain the use of weak, spastic muscles and stiff joints, but also to develop co-ordination in all movements. Ambulation of course is the main goal of the paralyzed patient, but even with the most stately good muscle strength that most such patients have or can develop, they are helpless and without any feeling of security because of their poor co-ordination and defective sense of balance.

The patience and personal attention given this group of patients can be realized by the authors' descriptions of the various exercises, games, and devices used. The very fact that more than 75 per cent of the patients eventually became able to walk up and down stairs indicates the satisfying gains which can be accomplished by a carefully supervised rehabilitation program.

José MARTÍN ALD
Asenjo, A., Perino, F. R., García, E. and Gallo, A.: *A Handred Cases of Tuberculomas of the Central Nervous System* (Cien casos de tuberculomas del sistema nervioso central). *Rev méd Chile* 1947 75 1.

Of the 7-125 neurosurgical patients observed from February 20, 1940 to June 31, 1945, 187 were diagnosed as having tumor of the central nervous system, and of these 100 (4.14 per cent) were harboring tuberculomas. Sixty five of these patients were either operated upon or came to autopsy; the rest were diagnosed clinically. The ages of these patients ranged from 19 months to 58 years and there was a predominance of the male sex among those with cerebellar localization and of the female sex

among those with hemisphere localization. In nearly every case the living conditions had been poor; there was a history of anergic maladies (scarletina, measles, grip, frequent colds) in 58 and in 69 there was a concomitant tuberculous lesion elsewhere (pulmonary or pleural in 48).

A special study of the relationship between the intracranial lesion was made in 35 patients. In 6 of these the lungs seemed to be without tuberculous involvement. However the roentgenological examinations in this study was unsatisfactory as the roentgenograms postulated a completely normal lung in 2 of 30 lungs which later proved to be tuberculous anatomically and in 4 of 11 also proved to be tuberculous anatomically.

In 11 instances the neurologic manifestations were preceded for from 3 months to 3 years by pleurisy. Some of the roentgenographic studies had been made weeks and even months before the death of the patient; however it is possible that the pulmonary lesion found anatomically after death was the result of dissemination from the central nervous system lesion itself. All in all however the authors conclude that they are justified in assuming that in a large proportion of these unfortunate cases the nervous localization resulted from hematogenous dissemination of the tubercle bacillus from the pulmonary lesion.

In 38 patients the tuberculoma was single and in 27 multiple. In 42 the localization was cerebral (25 confirmed, 17 presumed) in 33 cerebellar (26 confirmed, 7 presumed) in 9 the brain stem was involved (5 confirmed, 4 presumed), and in 6 the lesion could not be definitely localized. In all cases the shape and progression of the lesion tended to be irregular and differed from that of the new growths in that initially the lesion was not space constricting but invasive with tubercle bacilli identified as much as 2 cm from the macroscopic borders of the lesion.

The histology is that usually described except in that the proliferation of the microglia in early lesions is believed to have been described for the first time. This study of the histology, microglia, and connective tissue reaction was made in 8 cases by the method of Del Río Hortega. Later when the process did become of a space constricting nature the manifestations of increased intracranial pressure tended to dominate the picture and constituted the chief indication for early surgical interference. The operation for early surgical interference has in the authors' experience been a simple decompression usually of the occipital region. Of course an attempt might be made to remove the lesion en masse when 1.5 cm of healthy tissue could be left on all sides. This possibility was present chiefly in tuberculomas of the cerebellar hemispheres. In the cerebellar lesions there

were several disadvantages from the surgical standpoint. In the cerebellum the lesion does not tend to get well spontaneously by calcification as often as it does in the cerebral tuberculoma; there is more tendency to extend in all directions; that is, more tendency to produce a block in the circulation of the spinal fluid; and there is more tendency to extend to the meninges. In this localization removal of an entire lobe of the cerebellum may be attempted when the condition of the patient and the results to be expected would seem to justify the extensiveness of the procedure. For the tuberculomas of the brain stem little or nothing can be done. One may attempt an occasional decompression or in selected cases the operation of Torkindsen.

As regards the prognosis, 57 of these patients have been discharged. Of these 57 were operated upon and 31 were not. Of the operative patients, 3 were discharged in a very grave condition. Of the remaining 54, 3 are known to have died; of these 3 had been operated upon. Of the remaining 51 only 13 could be followed up subsequently. Of these 13, 4 had not been operated upon and of these 4, 3 stated that their neurologic symptoms had ceased. The remaining patient retains a tendency toward convulsive seizures which however can be controlled by luminal. The remaining 8 patients had been operated upon. Of these all report that their symptoms have entirely gone or at least diminished to a great extent.

Forty-three patients have died. Of these 30 had been operated upon.

In general, the cause of death has been the evolution of the encephalic tuberculoma which frequently resulted in tuberculous meningitis. Occasionally of course, this condition was complicated by the presence of lesions elsewhere in the body.

JORGE W. BRIDGMAN, M.D.

SPINAL CORD AND ITS COVERINGS

Munro, D.: The Rehabilitation of Patients Totally Paralyzed below the Waist with Special Reference to Making Them Ambulatory and Capable of Earning Their Living. *England J.* 35: 947-36-2-3.

In the present article the management of the urinary system in anatomic and physiologic transections of the cord and cauda equina is clearly explained. The correct use of tidal drainage is the foundation of proper bladder training. Tidal drainage permits the bladder to be filled and emptied with control of the intravesical pressure and prevents puddling of residual urine and overstretching of the bladder. The use of tidal drainage centers about the type of bladder one has. This is determined by cystometrographic studies. Its action depends on the hydrodynamics of the siphon. Siphonage is activated whenever a predetermined intravesical pressure has been reached. An airtight siphon system must be maintained during emptying. The siphon is broken by admission of air when the blad-

der is empty. The apparatus is then in a condition which permits the cycle to start over again.

Adjustment of the siphon curve is very important and the stage of the bladder recovery should determine the height of the siphon curve. Bladder associated with injuries of the spinal cord or cauda equina pass through four stages. Immediately after injury, the bladder is atonic and the siphon curve should be 1 or 2 cm. above the bladder level. The curve should be set at 3 to 5 cm. above bladder level for the autonomous bladder at 15 to 18 cm. for the hypertonic bladder and at 10 to 12 cm. for the reflex or automatic bladder. The latter height should also be used in the normal bladder of a patient who is unconscious from a head injury.

The author states that in doing a cystometrogram, it is important to imitate the natural bladder in the rate of filling. One should fill it in increments of drops rather than increments of 50 c.c. He advises a rate of about 90 drops per minute. When cystometrograms are done carefully lesions affecting the bladder are shown as follows:

A transaction between C4 and S2 shows an immediate atony. The detrusor muscle does not contract at all. The internal sphincter closes tightly and the external sphincter is relaxed. Any emptying is the result of leakage through the internal sphincter and occurs because of the elasticity of the bladder wall and not by any contraction. In the absence of spinal shock infection and hypoproteins, the bladder will proceed to the next stage, known as the autonomous stage which is characterized by ineffective aborted emptying contractions. The detrusor muscle contracts and forces urine through the tight internal sphincter. It is called autonomous because it is believed that the neural control is in the intramural autonomous plexus. The next is the hypertonic stage. It is characterized by frequent contractions of the detrusor. The internal sphincter opens with each contraction and closes during the intervals. The external sphincter responds reflexly. The final stage is the reflex or automatic stage. The bladder empties completely with each emptying contraction and is deprived of all inhibitory influences. It is the best end-result that can be obtained in transecting lesions, but should not be considered the end-result in nontransecting injuries. In the latter the patient has the ability to relax and contract the external sphincter.

Lesions that are complete and involve the sacral segments or roots, or which involve the parasympathetic plexuses and denervate the bladder depend on the intramural plexus for neuromuscular control. In such cases the end-result is the autonomous bladder.

Wherever possible, activity should be of the reflex type. The bladder capacity should be at least 300 c.c. To prevent genitourinary infection, the fluid intake should be at least 3,600 c.c. per day. Bladder training is easier when the patient is ambulant, but should not wait because the patient is forced to be in bed.

DANIEL REED, M.D.

SURGERY OF THE NERVOUS SYSTEM

PERIPHERAL NERVES

Telford E. D., and Mottershead S.: The "Costoclavicular Syndrome." *Brit M J* 1947 1 315

Although the syndrome arising from pressure on the subclavian or axillary artery and the accompanying brachial plexus as they pass from the thoracic inlet to the arm is fairly well known consistent agreement as to the site and mechanism of the compression is lacking.

One hundred and twenty cases of this "costoclavicular" syndrome were analyzed with regard to their history and findings at operation. The causes varied: scoliosis of the cervicodorsal spine bands from the scapulae medius to cervical ribs and cervical ribs of varying sizes. In many instances no definite etiology could be found. It was apparent from these patients that no one mechanical cause explained all the symptoms and findings.

A case history is presented of a 33 year old male with numbness and tingling when his left arm was depressed or hanging down at his side. Operation disclosed that the axillary artery was visibly compressed while in the symptomatic position by two heads of the median nerve.

Observations were made with regard to radial pulsation with the arms in various positions in normal individuals. Although decrease and obliteration of the pulse were noted in some individuals in various arm positions the highest percentage of various changes was found when adduction against force was tested. Investigation was undertaken on the anatomical findings of the clavicular and axillary regions of cadavers with especial reference to the neurovascular bundle and its relations with the arm in a depressed position (as when hanging by the side) the retracted position (as with displacement of the shoulder posteriorly) and with abduction and adduction. Dissection revealed the believed explanation of symptoms.

Pulse alterations when the arm is in a depressed position are explained by compression of the axillary artery by heads of the median nerve which anatomically encircle the artery. When the arm is abducted these nerve cords do not cause pressure sufficient to stop the arterial flow but the artery is occluded by edges of the subscapularis and the pectoralis minor muscles.

Interference with the brachial plexus involves different structures. With depression of the shoulder even the superior and middle plexus trunks are tightly stretched across the scapulae medius. When the arm is abducted or retracted the middle third of the clavicle pushes the plexus bundle backwards against the anterior border of the scapulae medius and if resistance such as a cervical rib or abnormal first rib were present compression might easily occur.

It is believed that in the majority of patients suffering from the "costoclavicular" syndrome the plexus crosses a cervical rib a tendinous band an abnormal first rib or the scapulae medius symptoms

are produced when the arm is depressed and are those from involvement of the lowest trunk. A smaller group has symptoms when the arm is retracted or abducted believed to be due to interference of the entire plexus by the clavicle.

That the "costoclavicular" syndrome is caused by compression of the neurovascular huddle between the clavicle and the first rib is not supported by any anatomical evidence. C. FARRAR, KIRKIN, M D

Maróttoli, O.R.: Traumatic Paralysis from Tractation of the Common Peroneal Nerve (Parálisis traumática por tracción del nervio clítico popliteo externo) *Bo Acad Argent* 1946 30 1187

Three clinical cases of peripheral paralysis of the common peroneal nerve are reported. In all the mechanism of trauma was the same: a traction injury of the nerve trunk however the etiology was different in each case. In one patient the immediate cause was a fall on the right side with a forced varus deformity of the right knee. In a second patient the cause was an aviation accident with prominence of the head of the peroneus and widening of the entire knee with healing of the fracture of this joint. In both these patients the sensory and motor paralysis were immediate to the injury. In the remaining case an injury to the femoral artery resulted in a huge hematoma of the corresponding thigh with flexure of the hip and knee joints and external rotation of the limb. The hematoma was evacuated at operation and the limb fastened down almost straight on a splint reaching from the hip to the ankle and the next day the paralysis typical of this injury had developed. In 2 of these patients intraneural injections of iodipin afforded fairly reliable roentgenograms of the condition present in the remaining case the roentgenograms proved entirely unreliable.

In the first of the cited cases the indurated anatomical section of the nerve over the peroneal head was excised and immediate nerve suture was done. The attempt apparently failed completely. In the 2 other patients the condition was more recent the degenerative changes not so advanced and the nerve was simply elevated and brought forward so that the nerve trunk would not be under tension. In 1 instance the head of the peroneus muscle was resected with satisfactory recovery of function.

JOHN W. BRECKMAN M D

MISCELLANEOUS

Kirklin, J. W., Chenoweth A. I. and Murphy F. I.: Causalgia. A Review of Its Characteristics, Diagnosis, and Treatment. *Surgery* 1947 31 321

The cases of 52 patients suffering from causalgia have been reviewed by the authors. They wish to define causalgia as a clinical syndrome associated with a lesion of a peripheral nerve containing sensory fibers, manifested by pain in the affected extremity. This pain is usually of a burning character and is usually located in an area corresponding to the

to the cutaneous distribution of the involved nerve. An integral characteristic of this pain, one whose presence is necessary in order to make the diagnosis, is its accentuation by certain disturbing features in the affected individual's environment.¹¹

The pathogenesis of causalgia is discussed with the various theories advanced by previous observers. No satisfactory explanation has as yet been advanced to account for the phenomena.

A good many of the reported cases were explored surgically but no difference in the pathological condition could be demonstrated in the patients with causalgia as contrasted with other patients with peripheral nerve injuries who did not have this syndrome.

Microscopic sections were made of resected neuromas and gliomas, but failed to prove conclusively that causalgia exists only in incomplete anatomic lesions. From the clinical standpoint, the majority of patients exhibited evidence of an incomplete nerve lesion.

The various types of pain described by the patients have been analyzed as well as the factors which tend to aggravate the discomfort.

Treatment has included neurolysis, which generally has been ineffective, periarterial sympathectomy is discussed, although it was not used in the present series.

The authors believe that the best method of treatment at this time is sympathectomy. In the case of the upper extremity approach is made by resection of a portion of the third rib. The sympathetic trunk is sectioned below the third ganglion with division of the gray and white rami between the second and third ganglia in their respective intercostal nerves. The central stump of the sympathetic chain is then sutured into the intercostal muscles below the second rib.

In the case of the lower extremity resection of the second and third lumbar ganglia with the intervening sympathetic chain has been employed. Preoperative procaine block of the sympathetic chain has been employed but was not considered as essential in making the diagnosis nor in making the decision to employ sympathectomy.

The results have been tabulated according to the degree of relief as classified by the authors.

HOWARD A. BROWN, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST
Gaston, F. A : Plasma Cell Mastitis Surgery 1947
21 208

During the 15 years since it was first described, plasma cell mastitis has been a subject of increasing interest to surgeons and pathologists. That the case is one of apparent rarity is attested by the fact that only 43 cases have been reported in the literature to date. The purpose of this communication is to call this disease to the attention of surgeons again, and to report 3 new cases 1 of which presented unusual complications.

The term plasma cell mastitis was first used by Ewing to describe a benign inflammatory disease of the nonlactating breast. The first published report in which this term was used was presented by Cheate and Cutler in 1941 and was based on cases observed at the Memorial Hospital for Cancer and Allied Diseases, New York, New York. Two years later Adair presented detailed reports of the 10 cases observed at the same institution up to that time. Since these preliminary reports a number of additional contri-

butions have been made in the American literature. The importance of plasma cell mastitis lies in the case with which it may be confused with carcinoma. The disease occurs well within the age limits when in multiparous women and the interval since the last published reports the disease has invariably occurred in lactation has averaged from 1 to 5 years.

Adair has pointed out that the natural history of the disease may be divided into two phases the acute and the residual. The acute phase consists of the inflammatory reaction involving all or a portion of the breast, often associated with increased local heat, redness and mild tenderness. This phase is transient and the symptoms are usually so mild that the patient does not seek medical advice. After a variable period, ranging from a few weeks to several months the residual phase consisting of a non tender tumor is noted. The tumor is at times accompanied by discharge from the nipple which is variously described as watery, creamy, white or puriform. Nipple discharge was noted in 12 of the 34 reported cases in which these data were mentioned. In none of these cases has a bloody nipple discharge been noted, although in 1 case presented, such a bloody discharge was present for 5 months preceding operation.

Examination of the involved breast reveals a firm nontender tumor mass with an irregular and often ill defined border. The mass may occupy any portion of the breast but usually it partially underlies the areola. The nipple is retracted and the overlying skin is edematous which gives a typical peau d'orange appearance such as is seen in malignant lesions. The axillary lymph nodes are usually enlarged. Signs of local inflammation are entirely lacking.

The physical findings in plasma cell mastitis may so closely resemble those of carcinoma of the breast with attachment to the skin and with axillary metastases that many cases have been reported in which radical mastectomy was done without preliminary microscopic study of the biopsy material. The diagnosis may be suspected, clinically by eliciting a satisfactory history of the mild acute phase of the disease.

The gross pathologic lesion of plasma cell mastitis consists of single or multicentric nodules usually of a yellowish brown color occasionally with liquefaction, and forming abscesslike cavities.

On microscopic examination the most striking feature is the massive infiltration of the glandular and interstitial spaces with plasma cells. In some cases these are found in solid sheets cords and in round or ovoid masses. Foreign body giant cells are usually present sometimes in great numbers, which makes the differential diagnosis from tuberculosis a matter of concern.

A diffuse overgrowth of periductal connective tissue often causes partial obliteration of the duct lumen, and by extending into the supporting tissue accounts for the retraction of skin and nipple which is so commonly noted clinically. Dilated ducts often filled with cellular debris desquamated from the lining epithelium. Plasma cell mastitis may be indistinguishable from plasma cell tumor of the breast.

From the clinical standpoint it would seem that such symptoms as tumor nipple discharge and skin and nipple retraction could be satisfactorily explained on the basis of epithelial hyperplasia and periductal fibrosis. Perhaps the only part of the clinical picture which might be attributed to the plasma cell reaction is the early acute phase described by Adair.

From the histologic standpoint it is well known that plasma cells are found in a great variety of diagnostic processes in which they are considered important only as indicating the presence of an inflammatory process of long duration. Therefore if the plasma cell reaction is merely incidental to some other pathologic process the advisability of using the term plasma cell mastitis in this nomenclature of using the term this manifestation, which places stress on the other suffix to point out that plasma cell reaction has been made that plasma cell reaction be used as the same time the pathologic condition which may have elicited it should be given. Thus, case 1 might be termed glandular cystic hyperplasia with plasma cell reaction or chronic mastitis with plasma cell reaction while case 2 could properly be termed comedocarcinoma with plasma cell reaction.

In case 1 there was a sanguineous nipple discharge in view of the marked hyperplasia of the epithelium along the ducts it seems probable that this symp-

tom will be encountered in only a small percentage of cases.

Case 2 is of particular importance because it illustrates the concomitant development of a mesenchymoma in a breast which was the site of a plasma cell reaction. While this is the first case that has come to the author's attention in which the condition coexisted the epithelioid periplasmic cell by all authors suggests that such a combination is more than coincidence. The case together with that reported by C. W. Cutler in which the cause or microscopically identical histioma is used as a plasmacytoma, suggest that plasma celloma is while usually a benign disease has distinct malignant potentialities which may develop either possibly both of two directions as a malignant epithelial neoplasm if the metastatic nature is probably the result of differentiation of the hyperplastic epithelial cells or as a malignant plasmacytoma if additional factors intervene. Clark observed 2 cases in which local recurrence without distant metastases followed the removal of the tumor mass.

These observations would seem to lend the problem of treatment to require an immediate microscopic examination of frozen sections of the tumor to be carried out in all but a few cases. In the presence of which the clinical features are characteristic of malignancy. When the frozen section plasma celloma is established histologically, myeloma treatment would seem to be operation followed by at least 1 year of observation. If the etiology and natural history of the disease Section II myeloma part of the breast should then be carefully studied for evidence of malignancy. If evidence of local frequent removal of the peritumoral muscles and radical lymph node section are of course indicated. Even though histologic evidence of malignancy is not found, careful follow up examination for evidence of local or distant recurrence should be made for several years following the operation.

TRACHEA, LUNGS, AND PLEURA

Miscall, L., and Harrison A. W. Thoracic Surgery in a Hospital Center. *C. Surg.* 94: 33.

Thoracic injuries fall into two large groups. Those in the first group demand immediate attention to save life and present problems concerned with the control of hemorrhage and the re-establishment of cardiorespiratory function. Those in the second group do not threaten life immediately and some delay in treatment is permissible. The problems they present involve the early maximal restoration of normal anatomic and physiologic relationships.

Operative and nonoperative measures are used in both groups but they are not mutually interchangeable. Conservative measures should be pushed to the limit when they will suffice. When they fail or are unsuitable operative approach is indicated. Success will be greatest when familiar with

with and regard for principles governing the application of both the operative and nonoperative principles and possibilities of the few of surgery needed.

HEART AND PERICARDIUM

Blum, R. J., Vandam, L. D., and Gray F. D. Jr. Physiological Studies in Congenital Heart Disease. Results of Preoperative Studies in Patients with the Tetralogy of Fallot. *Ann. Surg.* 117: 117-124, 1943.

The volume of blood flow through the pulmonary arteries was calculated in a total series of 120 patients with pulmonary stenosis according to the following formula:

$$\frac{\text{Oxygen content (ml per cent)}}{\text{Oxygen content pulmonary artery (1 percent more)}} \times \text{Oxygen content pulmonary vein (100 percent)}$$

In 35 patients with the tetralogy of Fallot the pulmonary artery per square meter of body surface was between 300 liters per minute which is normal cardiac output. The systemic blood flow was calculated according to the following formula:

$$\frac{\text{Oxygen volume (ml per cent)}}{\text{Oxygen content arterial blood (10 percent more)}} \times \frac{\text{Oxygen content of venous blood (1 percent more)}}{\text{per square meter of body surface}}$$

Cardiac output in 35 patients with the tetralogy of Fallot showed the rate of the systemic circulation to be increased as compared to normal. As a result of the increased flow through the peripheral circulation the difference between the oxygen content of the mixed peripheral arterial and venous blood was found to be normal. The total blood flow was approximated by the formula for the cardiac output and the systemic blood flow was calculated according to the following formula:

A comparison of the data obtained from the flow with those obtained for the flow in the pulmonary artery showed that the former exceeded the latter by from 0 to 60 liters per minute. In the tetralogy of Fallot there fore some flow returns to the mixed venous blood, which is pumped through the stenosed pulmonary artery. It is the flow through the interventricular septal defect and the overriding aorta directly into the systemic circulation. The overall direction of the blood flow is therefore was from right to left. However there is some concomitant flow from left to right through the septal defect. This is shown by the observation that the oxygen content of mixed venous blood exceeded that of the right atrium in many cases. The variations in systemic flow in patients with the tetralogy of Fallot are related to the degree of pulmonary stenosis and the size of the interventricular septal defect.

The pulmonary capillary flow (total pulmonary flow) was calculated according to the following

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of blood reaching alveoli (vol. per cent) minus CO}_2 \text{ content of pulmonary vein blood (vol. per cent)}} \times 100$$

In most younger patients the values obtained agreed closely with those determined for pulmonary artery flow. In most older patients the pulmonary capillary flow exceeded the pulmonary artery flow which indicated that the lungs received blood from sources other than the pulmonary artery. Direct observations of the collateral circulation during operation confirmed these findings. It is probable that the collateral circulation to the lung is an important factor in the physiological adjustment of these individuals to their abnormally low pulmonary artery flow.

Intracardiac and systemic blood pressures were obtained in a series of 22 patients with clinical and physiological evidence of the tetralogy of Fallot. The right intraventricular systolic pressure was elevated in 21. The pressures recorded ranged from 20 to 110 mm. above the normal values of 18 to 28 mm. of mercury. The diastolic pressure in the right ventricle was elevated in 8 cases. In many cases systolic pressure in the femoral artery was of the same order as that in the right ventricle. Changes in the peripheral resistance occur as a compensatory response to the alterations in flow.

Oxygen consumption in the great majority of patients with decreased effective pulmonary flow is reduced. The basal metabolic rate calculated from the figures obtained ranged as low as -48. The basal metabolic rate of patients with reduced effective pulmonary blood flow increased considerably following the performance of the Blalock-Taussig operation which raises the pulmonary flow.

During the standard exercise test the ratios of oxygen consumed and of carbon dioxide produced per liters of ventilation decreased, while the arterial oxygen saturation dropped immediately following

the exercise. Simultaneously the arterial carbon dioxide content increased. Inadequate effective pulmonary blood flow which causes the decline in the ratios of oxygen consumed and carbon dioxide produced per liters of ventilation, cannot be responsible for the changes in the arterial blood gases. Even in severely anoxic patients the blood reaching the left auricle is fully saturated with oxygen. It is therefore probable that shunts through the inter-ventricular septal defect and the overriding aorta are responsible for the fall in oxygen saturation and the rise in carbon dioxide content of the arterial blood during exercise.

SAMUEL KARN M.D.

ESOPHAGUS AND MEDIASTINUM

Schafer, P. W., and Kittie, C. F.: Esophageal Leiomyoma. *J Am Med Ass.*, 1947 133 1202

Benign tumors of the esophagus are very rare. Moersch and Harrington report 44 in 7,459 necropsies (0.59%). At the University of Chicago 11 were found in 6,001 necropsies (0.18%). About 200 cases have been reported. These include 12 varieties of tumor of which myoma is the most frequent.

Myomas are most frequent in the distal third of the esophagus. They are multiple in about one quarter of the cases and produce symptoms in about one tenth of the cases, i.e. only when the tumor is large. The symptoms are vague and indefinite pain, they are nonpathognomonic. Dysphagia is rare.

Four cases of surgical resection have been reported. The authors' case is the second successful surgical resection. The tumor was large (178 gm.) and had developed in the lower esophagus giving symptoms of intermittent pain in the right lower part of the chest over a period of 18 months and of acute pain for 2 days. The preoperative x-ray diagnosis was diaphragmatic hernia which was also present.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Christopher F., and Penna, O J: *The McArthur Operation for Inguinal Hernia Surgery* 947
31 48

In evaluating a method of inguinal herniorrhaphy one must consider the type of hernia, the type of operation, the experience of the surgeon, the type of suture material, the age and occupation of the patient, the time of ambulation, and the care and accuracy of the follow up studies. Unfortunately in many published series the follow up data are based on questionnaire replies rather than actual examination.

In the last 4 years the authors have done 203 direct and indirect herniorrhaphies by the McArthur technique.

The technique employed by the authors requires silk throughout. The sac is transected and ligated and the stump is fixed or allowed to retract under the inferior oblique muscle. In small direct hernias the sac may not be opened. The cord is transplanted subcutaneously. The conjoint tendon and usually the transversalis fascia are sutured to Poupart's ligament by a continuous fascial suture prepared from the mesial border of the split aponeurosis of the external oblique muscle. One end of this suture is left attached to the symphysis pubis. When the cord is reached the suture is doubled back for a few bites. The end is securely anchored with 5 or 6 interrupted 00 silk sutures. With the cord elevated, the mesial border of the split aponeurosis of the external oblique muscle is sutured to the inguinal ligament with interrupted silk sutures. The outer layer of the aponeurosis is imbricated over it. The aponeurosis of the external oblique is imbricated above the cord, the lateral flap being uppermost. The opening for the cord is made large enough to admit a Kocher director in addition to the cord. Patients are encouraged to get out of bed on the first or second postoperative day and are sent home between the fourth and eighth days.

McArthur first described this operation in 1901. Since then Bigsard, Sachs, Joyce, and Ryan have endorsed the procedure.

One hundred and thirty hernia operations were done on 112 patients who reappeared for follow up examinations. Of these 71 were for indirect hernia, 31 for direct hernia, 7 for recurrent hernia, 2 for direct-indirect hernia, and in 1 case the hernia had no sac. In 18 cases the type of hernia was not specified. There were 106 male and 6 female patients with an average age of 46.6 years, the extremes being 19 and 75. The follow up period averaged 24.2 months, the extremes being 3 and 61 months. There were 3 deaths in the series: 1 from pulmonary embolus and 1 from pulmonary thrombosis. There were 4 known recurrences, a percentage of 3.1. Three patients had wound infections.

The authors list the recurrence rates of various surgeons who reported using this technique, and the overall recurrence rate was 3.1 per cent for 705 operations. Four surgeons using the Galle operation had a recurrence rate of 24.8 per cent for 1,139 operations. A comparison is then made with the results of 10 surgeons who used a nonfascia operation, in this group the recurrence rate was 7.1 per cent for 6,379 operations.

The authors then give short abstracts of the case histories of the 4 patients who developed recurrences.
ROBERT R. BIGSARD, M.D.

GASTROINTESTINAL TRACT

Benedict, E. B.: *The Limitations of Roentgenology and Gastroscopy in the Diagnosis of Diseases of the Stomach; An Analysis of 53 Proved Cases. Gastroenterology* 947 8 5

Gastroscopy supplements roentgenography in examinations of the stomach and in no way are the two competitive. In certain instances the roentgen examination appears to be superior to gastroscopy and in other instances the reverse is true.

The chief causes of failure in gastroscopy are mechanical. Once the gastroscope gets a satisfactory view of the lesion, his chances of reaching a correct diagnosis seem to be greater than those of the roentgenologist. Greater diagnostic accuracy is attainable when both methods are used co-operatively than when either method is used alone.

The author presents a series of 53 cases of proved gastric disease, including benign and malignant lesions. Case histories illustrate the limitation of x-ray and/or gastroscopy in each of various types of disease. In 19 proved carcinoma cases, the x-rays and gastroscopy both led to correct diagnoses in 10 instances. The diagnoses were both incorrect in only 1 case. In 8 cases, one method was more accurate than the other: 6 times in favor of gastroscopy and twice in favor of the x-rays. The author attributes this good showing for gastroscopy to recent mechanical advances. These improvements include the possibility of changing the angle of the mirror in American gastroscopes, and proximal control of the flexible part in 1 of the English instruments.

HAROLD LATTIN, M.D.

Farnett, F.: *Lymphogranulomatosis Primary in the Stomach (Linfogranulomatosis Isolata e primitiva dello stomaco). Arch. Ital. med. exp. 619*
947 3 3

A review of the literature shows that 16 cases of lymphogranulomatosis involving the stomach alone have been reported. To this number Farnett adds 1 in which a 38 year old man presenting the clinical picture of a gastric ulcer died suddenly of hemorrhage. Autopsy revealed changes in the stomach

wall suggestive of linitis plastica, with involvement of the regional glands. The mucosa of the stomach was found to be greatly thickened reaching at some places a thickness of 1.5 cm.

Microscopic examination of the stomach and lymph glands confirmed the impression of a malignant granuloma with the primary lesion in the stomach. The histological character of the affected tissue conformed to the phlogistic infiltrative category.

EDITH B. FARNSWORTH, M.D.

Orr, T. G.: A Modified Technique for Total Gastrectomy. *Arch Surg* 1947 54 279.

The author describes a new modification of esophagojejunal anastomosis in total gastrectomy. It is essentially an adaptation of the Roux-en-Y technique. The end of the distal portion of the jejunum is closed below the ligament of Treitz. It is then brought up either through the transverse mesocolon or in front of the colon and connected to the end of the esophagus by an end-to-side anastomosis. The proximal end of the jejunum is then anastomosed into the side of the jejunum below the transverse mesocolon.

The advantages of the technique described are (1) the direct entrance of the food into the jejunum distal to the anastomosis without filling of the proximal part of the jejunum as in the loop operation, (2) elimination of distention or delay in emptying of

Fig. 1. (Orr) Technique of total gastrectomy. The insert shows the type of paramedian incision used. The ligament of the left lobe of the liver has been severed and sutured beneath the right side of the abdominal wall to retract the left lobe. An incision has been made for the formation of peritoneal flaps and exposure of the esophagus.

the proximal portion of a loop, and (3) elimination of any regurgitation of the duodenal contents into the esophagus. The postoperative progress in 4 of the cases recorded was uneventful. In the fifth the

Fig. 2. Technique of total gastrectomy (continued). The jejunum is divided 15 cm. below the ligament of Treitz. The end of the distal portion of the jejunum is closed, and the first row of sutures and lines of incision are shown in the esophagus and jejunum as the first step in end-to-side esophagojejunostomy.

Fig. 3. (Orr) Technique of total gastrectomy (concluded). The end-to-side esophagojejunostomy is completed showing peritoneal flaps sutured to the jejunum over the anastomotic line of suture. Lateral sutures have been placed to fix and suspend the jejunum. Postcolic end-to-side jejunojejunostomy is completed. The mesentery of the colon is sutured to the jejunum and the mesentery of the jejunum to close the defect in the mesocolon.

patient died following a hemiplegia on the fortieth postoperative day.

The author suggests that with constantly improving method of supportive treatment for patients submitting to surgical procedures, and improvement and standardization of technique it seems reasonable to predict that the mortality rate for total gastrectomy in the future will not exceed from 10 to 15 per cent.

HAROLD LAUFMAN, M.D.

Moore, F. D., Chapman, W. P., Schultz, M. D., and Jones, C. M.: Resection of the Vagus Nerve. *J. Am. Med. Ass.* 1947, 33: 74.

Of 33 patients who were treated by vagotomy or vagus resection and observed for from 3 months to 2 years, 29 have shown good results clinically. Healing of the ulcer: the most uniform feature of this series. Recurrences have not been uncommon, but transient undesirable side effects occur and are found in about 10 per cent of the patients.

The decrease in fasting acidity and motility, which is so readily demonstrable after the operation, gradually returns toward normal until, at the end of a year, little abnormality of these factors can be found. The secretory response to insulin-induced hypoglycemia

remains abolished in most cases, and the clinical well-being of the patients also appears to outlast the duration of the early secretory and motility changes. This strongly suggests that, although the immediate relief of pain and the healing of the ulcer may be due to changes in the fasting motility or the secretion produced by the operation, any prolonged relief which the surgical procedure confers on the patient is due to some more subtle effect. This more subtle effect is probably traceable to severance of those nerve pathways which communicate the patient's adaptive reactions from brain to stomach. In patients suffering from peptic ulcer, impulses transmitted over these pathways in response to environmental situations often result in exacerbation of the disease. After resection of the vagus nerves, such impulses cannot reach the stomach and exacerbations of the ulcer do not occur.

SAMUEL KERN, M.D.

Evans, E. I. and Bigger, J. A.: Intestinal Strangulation. *J. Am. Med. Ass.* 1947, 33: 513.

Strangulation of the small bowel was responsible for more deaths in the hospitals of the Medical College of Virginia in the years 1941 to 1946 than appendicitis with rupture and peritonitis. Differentiation of simple obstruction and strangulation obstruction is paramount. Pain is the commonest symptom in obstruction of the small bowel. There is a dramatic onset of pain in strangulating obstruction. The incidence and frequency of repeated vomiting is greater in patients with strangulating obstruction. The patient with a strangulated obstruction usually appears extremely ill continuously.

The authors explain in detail the sign of "position of relief." It is thought that this "position of relief" reduces traction on the mesentery. Furthermore, this one position of relief is highly suggestive of strangulation of the bowel. Only after inspection, palpation, percussion, auscultation, and pertinent laboratory data can one make the proper diagnosis. There is no significant difference in the general appearance of the abdomen in the two types of obstruction. Abdominal palpation showed abdominal tenderness to be present in all cases of strangulation. Tenderness and muscular spasm usually mean strangulation. A palpable mass further clinches the diagnosis. In the laboratory data, a rising leucocyte count is suggestive of intestinal strangulation. A pulse rate above 100 in the earlier hours generally indicates intestinal strangulation.

In the management of intestinal strangulation a transfusion of whole blood is mandatory. Evidence indicates that some 1,500 to 2,000 c.c. of whole blood will be required to restore to normal the blood volume in this type of patient. A Levine tube should be inserted into the stomach and the stomach emptied by suction drainage. Dehydration is combated by intravenous isotonic solution of sodium chloride. Surgical operation should be carried out as soon as the patient is prepared, care being taken that not too long a time elapses between onset of the con-

SURGERY OF THE ABDOMEN

tion and operation. Shock and peritonitis in acute strangulation of the small bowel are usually due to avoidable delay in surgical intervention. Early diagnosis and treatment is the safest course.

Tables are presented which give all the data on the clinical cases and the physical and laboratory observations in intestinal strangulation. Table 3 lists the differential criteria in simple obstruction and strangulation. RICHARD J. BENNETT, JR., M.D.

Magney P. H. Acute Intussusception in Infancy and Childhood. *Minnesota M.* 1947 30: 257

The author presents an analysis of 58 cases of acute intussusception in infants and children admitted to 2 hospitals during the 25 year period from 1921 to 1945 inclusive.

The age incidence was as follows: 74 per cent of the patients were under 1 year of age; the highest incidence being at 6 months; 95 per cent were under 3 years. The youngest was 7 days old; the oldest 12 years. There were 35 males and 23 females.

Meckel's diverticulum in 2 patients was the only pathologic condition found at operation which could be considered as an etiologic factor. Vomiting was the most frequent symptom, occurring in 88 per cent of the patients. Cramplike intermittent abdominal pain was present in 70.7 per cent and bloody stools were noted in 63.8 per cent. Seventy-three per cent of the patients presented all of these symptoms and all had at least one of them.

Fever was present in 38 per cent of the patients. Abdominal masses were noted in 60 per cent and rectal masses in 20 per cent.

Nonoperative and postoperative measures to be used. Preoperative and postoperative measures to combat dehydration, toxicity or shock are essential and should be under the direction of a pediatrician.

Ether is the anesthesia of choice and was used by the open drip method, in 53 of the 58 operations. A right rectus incision was routinely made.

The types of intussusception were as follows: ileocolic in 49 patients; ileoileal in 5; colocolic in 4. The operative procedure was manual reduction in 49 patients. Additional operative procedures were appendectomy in 10 patients; some method of fixation of the intestine in 5 patients; and appendectomy and fixation in 1 patient.

Intestinal resections were performed in 7 patients. Five of these were combined with anastomoses, 1 with a double enterostomy and 1 with a single enterostomy. In 1 patient an anastomosis was made around the irreducible mass.

The intussusception occurred in 2 patients and a second operation was necessary.

The duration of symptoms is the greatest single factor responsible for the high mortality. The mortality rate rose from 18 per cent for the first day to 23 per cent for the second day and to 50 per cent for the third day.

Deaths in relation to the types of intussusception were as follows: 2 deaths in 5 cases of ileoileal (40

per cent mortality); 12 deaths in 49 cases of ileocolic (24.7 per cent mortality); and 1 death in 4 cases of colocolic intussusception (25 per cent mortality).

Of 49 patients treated by manual reduction of the intussusception, 8 died, a mortality rate of 16.3 per cent. Intestinal resections in 7 patients resulted in 4 deaths, a mortality rate of 57.1 per cent. There has been a progressive improvement in results in recent years. The first 10 years showed a mortality rate of 46.7 per cent as compared with 18.1 per cent during the last 15 years. There were 2 deaths among 17 patients operated upon in the last 5 years, a mortality rate of 11.8 per cent. EMMETT E. ARNHEIM, M.D.

Silverman D. N. and Leslie A.: Intestinal Tumors. *J. Am. M. Ass.* 1947 133: 904.

Six cases of inflammatory intestinal tumors of specific nature occurring as a complication of amebic or bacillary involvement of the intestine are reported. Amebic granulomas occurring as they do only in the colon cannot be distinguished radiologically from cancer. In most of the cases hitherto described and in 2 of those reported in the present article, the patients were subjected to unnecessary laparotomy because of the preoperative diagnosis of colonic neoplasm. Since there is such variation in therapy and prognosis it is important to distinguish amebic granulomas from malignant tumors.

Special attention is called to 1 case of ileocolic inflammatory tumor occurring in bacillary dysentery and 1 such tumor in combined amebic and bacillary disease. Although the occurrence of inflammatory tumors in the course of chronic bacterial dysentery is rare, such cases may be expected to occur with greater frequency in the future because of the present widespread dissemination of infection due to *Bacterium dysenteriae* throughout the United States.

The outstanding and almost universal characteristic of amebic granulomas is their response to specific therapy. There is a rapid resolution of large tumors after the administration of emetine hydrochloride. An amebic granuloma in which extensive fibrosis has taken place may require surgical intervention but this should not be considered until thorough amebicidal therapy has proved inadequate. In 3 of the cases reported, large tumors disappeared after medical therapy alone. A large granuloma associated with infection with *Bacterium flexneri* did not respond to autogenous vaccine therapy and surgical resection was successfully performed.

Rectal scrapings or even a biopsy if a tumor is within reach of the sigmoidoscope, can be diagnostic. If amebic granulomas are considered in the differential diagnosis of tumors of the colon, careful examination of the saline-purged stool will in most instances of amebic tumors, reveal the protozoan. In isolated instances, as in one of the cases of this series, the amebas are present only in the depths of the tumor mass and elude the parasitologist. Although it is contrary to scientific procedure to give specific treatment without a specific diagnosis, a case such

as this, which terminated fatally following surgical resection, gives one pause and in the younger age group at least, when the history is at all suggestive of dysentery a therapeutic test might well be justified. The problem of amebic granulomas is no longer regional, since cases are reported from northern areas.

JOHN L. LINDGREN, M.D.

Boriani, G.: Roentgenologic Picture of Bulbar Duodenitis of the Ulcer Type and Its Medical-Legal Importance (Quadro radiologico della duodenitis bulbare a tipo di ulcera sua importanza al fini medico-legali). *Radiol med Milano* 1947 33 15.

The clinical picture of bulbar duodenitis is revealed by a heavy feeling, pain, and a burning sensation melena may also be present. Usually the roentgenologic diagnosis is easy: small opacities or small cul-de-sac defects are seen between the mucous mucosa or otherwise, small ulcerations. Edema is a type of duodenitis however in which edematous nodules are arranged so as to make it difficult to differentiate between bulbar duodenitis of the ulcer type and a true duodenal ulcer.

It is noted, according to Akerlund, that the typical duodenal ulcer presents a three leafed clover appearance with 3 leaves on the base toward the pylorus and the third leaf above. In other words, a sessile clover without a stem. In bulbar duodenitis the picture is at times similar which may cause confusion, but there is a substantial difference in that either the clover has an inverted appearance with the 3 leaves above and 1 leaf toward the pylorus or if the clover is analogous in position to that found in duodenal ulcer, there is a small stem present which is not found in duodenal ulcer.

The authors cite the importance of this differentiation because duodenitis might easily be caused by the patient's eating an irritative substance, and, thus, a picture of duodenal ulcer might be produced intentionally for personal reasons. Many such cases were observed during the war in which there was no evidence of duodenal bulb deformity when the person was recalled back without warning in several days.

LUCIAN J. FRODOFF, M.D.

Rogers, H. M., Keating, F. R., Jr., Marlock, C. G., and Barker, N. W.: Primary Hypertrophy and Hyperplasia of the Parathyroid Glands Associated with Duodenal Ulcer; Report of an Additional Case, with Special Reference to Metabolic, Gastrointestinal, and Vascular Manifestations. *Arch. Int. M.* 1947 79 307.

A case is reported in which pronounced clear cell hyperplasia of the parathyroid glands and primary hyperparathyroidism were associated with healed duodenal ulcer. The parathyroid glands weighed 47.56 gm. Peripheral gangrene developed as a terminal event. Death resulted from renal insufficiency secondary to nephrocalcinosis. Pancreatic lithiasis and mild osteitis fibrosa cystica were also disclosed at autopsy. An unusual type of necrosis of the arterial

walls, with intimal calcification, appeared responsible for the peripheral gangrene. Gastrointestinal symptoms, which were presumed during life to be due entirely to ulcer, appeared in retrospect to have been manifestations of severe hyperparathyroidism.

Shallow, T. A., Wagner, F. B., Jr., and Morgan, W. B.: Enterogenous Cysts of the Duodenum. *Surgery* 1947 53 1.

Enterogenous cysts of the duodenum, in spite of their rarity should be recognized by the surgeon when they are encountered unexpectedly at laparotomy and a knowledge of the proper methods of treatment is essential.

The authors report the case of a 12 year old boy who had suffered recurrent attacks of high intestinal obstruction since the age of 1 year and who passed tarry stools prior to admission. His abdominal examination was negative. Laboratory studies revealed a moderately severe anemia and stools positive for blood. Roentgenograms of the upper gastrointestinal tract showed an elongated filling defect in the second portion of the duodenum with a slight irregularity of the defect, suggestive of ulceration. These findings were interpreted as being suggestive of a leiomyoma with ulceration in the second portion of the duodenum or of a gastric polyp prolapsed into the duodenum.

After correction of the anemia the patient was explored. Palpation revealed a semicircular mass about 3 cm. long in the second portion of the duodenum along the mesenteric border adjacent to the pancreas. Exploration through a gastrotomy incision showed no polyps nor stomach abnormality but, instead a smooth, circumscribed, semicircular mass arising from the wall of the second portion of the duodenum and projecting into the lumen. The duodenum was then opened opposite the mass, and the ampulla of Vater and the pancreatic duct orifice were identified at the upper border of the mass. From within the duodenum a transverse incision was made through the mucosa overlying the mass. With some difficulty the mass was excised intact from its submucosal position without rupturing through the posterior duodenal wall. The mucosal and longitudinal incisions were closed, thus re-establishing duodenal continuity. The gastrotomy wound was then closed before closing the abdomen in layers, without drainage. The operation lasted 1 1/2 hours and the patient was given 500 c.c. of blood.

The pathological specimen was a thin walled cyst, 2.5 by 2 by 1.5 cm., containing thick cloudy fluid. The lining was a duodenal type of mucosa and outer wall muscularis.

The postoperative course was uneventful, and follow-up roentgenograms at 4 months showed a normal mucosal pattern of duodenum at the site of the cyst. The patient was entirely well 1 year after operation.

The authors were able to collect only 13 other cases of enterogenous duodenal cysts from the world literature. These are briefly analyzed. In 10 cases the cysts occurred between birth and 4 months of age.

The oldest patient was 15 years of age. There were 3 males and 9 females.

Lewis and Thynge believe these cysts arise from detachment of knoblike diverticula which occur along the entire intestinal tract of embryos of man, the pig and the rabbit. Hughes and Jones believe that sequestration of embryonal intestinal epithelium early in fetal life may give rise to enterogenous cysts. Maddox favors the theory of origin from a vacuole arising during the so-called solid stage of the intestine which falls to gain communication with the developing lumen.

Although there are wide pathological variations these cysts are all adherent to some portion of the duodenum, all contain fluid and their walls are composed of all layers of the intestine.

In the authors' series 5 cysts were located in the first portion and 5 in the second portion of the duodenum. They were round or pear-shaped and from 2 cm. to 15 cm. in diameter. The contained fluid was clear and pale or cloudy and dark. In no case was a communication with the lumen demonstrated.

Multiple congenital abnormalities including multiple intestinal and biliary cysts, accessory spleens, transposition of the viscera, and a mediastinal cyst were observed in several cases.

Histologic examination of these cysts reveals a mucosal lining usually duodenal in type. The mucosal lining may at times correspond to other levels of the gastrointestinal tract. The smooth muscle coat is a constant feature of the lesion and it is adherent to or continuous with the muscularis of the duodenum, allowing no cleavage plane.

Enterogenous cysts are seen much more frequently in the ileocecal region.

Clinically these duodenal cysts produce obstructive symptoms by encroaching on the lumen. One may elicit a history of vomiting, intermittent colicky pain, a palpable mass, visible peristalsis, melena, anemia, and possibly jaundice depending on the size and position of the tumor and the degree of pressure and necrosis of the duodenal mucosa. X-ray examinations of the upper gastrointestinal tract, colon and kidney may aid in the diagnosis.

If a fluctuant mass is palpable, omental chylous, dermoid, pancreatic and choledochal cysts must be considered in the differential diagnosis. If the mass is more resistant, it may resemble hypertrophic pyloric stenosis, intussusception, renal tumor or leiomyoma.

In the absence of a mass, pylorospasm and congenital duodenal diverticulum, atresia, or adhesive bands must be considered.

Surgery is the treatment of choice and the method employed must be determined by the individual case. Excision of the cyst is usually mechanically impractical because of the continuity of the cyst and duodenal muscle layers. Injury to vessels during excision may lead to bowel wall necrosis, since the cyst and duodenum have a common blood supply. Excision from within the lumen was successfully carried out by the authors, and from without by Rogers. Resection of the duodenum containing the cyst and re-establishment of continuity is too formidable a procedure

in infants and in debilitated patients and not feasible when it would involve the pancreatic and biliary ducts. In poor risk patients window anastomosis to the adjacent duodenal lumen or to a loop of jejunum the segments of which are joined in an enterocostomy to divert the intestinal stream may successfully be carried out. Marsupialization can be undertaken if the cyst is large. Aspiration or catheter drainage is to be condemned. In 1 case gastroenterostomy alone to relieve obstruction was successful.

The high mortality (50%) is due to the early age of the average patient, and the frequently poor preoperative condition of the infants. The immediate and ultimate prognosis is good in the older patients (all 4 of the older patients recovered following surgical treatment). It is hoped that by more competent pre and postoperative care the higher mortality among infants can be reduced.

ROBERT R. BIGLOW, M.D.

Andrucci, M.: Osteopetrosis and Cancer of the Duodenum (Osteopetrosi e cancro duodenale). *Arch. Ital. chir.*, 1946 68 399.

The author describes a case in which cancer of the duodenum coexisted with an eburnating osteosis diffused throughout the whole skeleton. Two types of osteopetrosis can be distinguished: one in the child which is hereditary or congenital and the other in the adult which is acquired. The lesions found in adults may be regarded as primary and not as late manifestations of pre-existent lesions for the anatomic picture observed in adult patients is substantially different from that observed in children.

The eburnation process may depend on such vascular alterations as obliterating endarteritis secondary to chronic bone inflammation in which the reduced vascular activity can provoke a gradual sclerosis of the medullar tissue and a higher deposition of calcareous salts.

All the regions affected by osteopetrosis in the author's case had reduced circulatory activity because of vascular lesions of luetic nature and mechanical obstacles provoked by the small metastatic embolisms of the tumor. These lesions might be found in all organs including the skeleton.

ARTHUR F. CIPOLLA, M.D.

Griffin, W. D., Silverstein, J., Hardt, H. G. Jr. and Seed, L.: Prophylactic Chemotherapy in Appendicitis. *J. Am. Med. Ass.* 1947 133 907.

The benefits of prophylactic administration of penicillin and sulfadiazine in war wounds and in many varieties of surgical procedures have been demonstrated beyond doubt. Many surgeons however hesitate to subject all their surgical patients to a rather stereotyped regimen of prophylactic therapy. The authors report the results of the routine systemic administration of penicillin and sulfadiazine in a series of 108 consecutive patients operated on for acute appendicitis in the Cook County Hospital, Chicago. The circumstances per-

mit fairly accurate comparison with series of patients treated in previous years since the only difference in treatment has been the introduction of the routine use of penicillin and sulfadiazine in the present series.

Twenty thousand units of penicillin were given intramuscularly with the preoperative medication. This was followed postoperatively by 20,000 units of penicillin every 3 hours for 4 days. The patients also received 1 gm. of sulfadiazine four times a day for 4 days postoperatively. If the patient was unable to tolerate oral medication 5 gm. of sodium sulfadiazine in 1,000 c.c. of saline or dextrose solution was given daily by the intravenous route. In children the dosage of penicillin was the same as in adults but the dosage of sulfadiazine was reduced in proportion to the age of the patient.

The 108 cases were classified as follows: (1) acute suppurative appendicitis 62 cases; (2) acute gangrenous appendicitis 7 cases; (3) perforated appendicitis 19 cases. There were 77 adults and 31 children. There was only 1 death in the series. This patient was a middle aged obese woman with hypertension, severe diabetes and symptoms of 5 days duration, who died in a diabetic acidosis that did not respond to insulin treatment.

A table shows the death rate following appendectomy for the years 1928 to 1932 as 7.6 per cent, for 1937 and 1938 as 3.9 per cent, and for 1944 and 1945 as 4.3 per cent, as compared with a mortality of approximately 1 per cent which occurred in the present series.

In addition to the reduction in mortality there was a concomitant observable reduction in morbidity. The patients were more comfortable, had less abdominal pain and less abdominal distention, and were able to tolerate a full diet at an earlier date. In the past the majority of patients with perforated appendicitis had considerable postoperative ileus with abdominal distention. Only 1 patient in this series had a paralytic ileus severe enough to warrant the use of Wangenstein suction. Three cases of intra-abdominal abscess and 1 case of pelvic abscess were observed in this series. These abscesses subsided spontaneously on the continuation of the routine administration of penicillin and sulfadiazine. The use of penicillin and sulfadiazine seemed to prevent the development of severe infection in the wounds. There were 9 instances of wound infections. There was a definite reduction in the duration of hospitalization. Since no organized effort was made to send the patients home at an early date this indicates in general a shorter and less complicated convalescence. JOHN L. LINDQUIST, M.D.

Bartlett, R. W.: Management of Colostomies in the Fifteenth Hospital Center (England). *Arch. Surg.* 1947 54: 269.

War injuries to the large bowel are complicated in a high percentage of cases by other major injuries. Before closure is attempted, care must be taken that colostomy spurs are adequately obliterated, and that

edema of the bowel and active infection of the wound are no longer present. Compound fractures of the pelvic bones with osteomyelitis and purulent drainage in the neighborhood of the colostomy are an absolute contraindication to repair as failure will result because of infection in the wound. If a suprapubic cystostomy and colostomy coexist, the former should be permitted to heal before closure of the colostomy is carried out in order to avoid continual soaking of the wound with urine.

During the period of evaluation and preparation, the patients were maintained on high proteins, high caloric diets with multivitamins and full correction of any existing anemia or hypoproteinemia. Barium enemas and proctoscopic examinations were performed especially in cases in which there had been a rectal wound. In order to be sure that a perforation no longer existed at the time of repair, immediately before operation the patient was placed on a non-residue diet for 3 or 4 days and mild catharsis was instituted. Frequent irrigations of both colostomy loops were carried out.

Many closures can be kept extraperitoneal. In the case of closure of sigmoid colostomies, the author has employed a medium calibered latex tube as a safety valve above the suture line. Subcutaneous drains were placed in most closure wounds for 48 hours postoperatively. Penicillin and sulfadiazine in standard doses were used in perhaps half of the cases in this series. Since the advent of succinylsulfathiazole, this drug has been used routinely.

Of 398 colostomies, 238 were closed by simple transverse closure of the loop or closure following spur crushing, while 60 were closed by end-to-end anastomosis. There was 1 postoperative death. The author explains that this excellent result was probably due to the fact that the patients were vigorous young men undergoing elective operation, and that unlimited supplies of such essentials as blood, plasma and chemotherapeutic agents are available throughout the preoperative and postoperative periods. HAROLD L. CHASE, M.D.

Spottiswood, B. I.: A Case of Lipoma of the Descending Colon (Sopra un caso di lipoma del colon discendente). *Riv. internat. clin.* 147: 947-951-1945.

A lipoma of the descending colon was found in a 26 year old male patient who had the following symptoms: a sensation of insufficient bowel evacuation, constipation followed by diarrhea, and, at irregular intervals, severe abdominal pain in the left lower quadrant, distention of the abdomen, nausea, and vomiting. X-ray examination revealed an obstruction.

Through a left pararectus incision, a tumor was discovered in the midportion of the descending colon. The bowel was opened, and a submucosal mass the size of an apple with a 2 cm. ulceration was resected. The bowel was exteriorized. Eleven weeks later an end-to-end anastomosis was performed, and the patient made an uneventful recovery. ARTHUR F. CROSSLAND, M.D.

Calmenson, M., and Black, B. M.: Surgical Management of Carcinoma of the Right Portion of the Colon with Secondary Involvement of the Duodenum, Including Duodenocolic Fistula. Observations on 8 Cases. *Surgery* 1947 21 476

In 8 cases seen between 1907 and 1945 carcinoma of the right portion of the colon with secondary malignant involvement of the duodenum was treated surgically at the Mayo Clinic. The diagnosis of a duodenocolic fistula is usually made roentgenologically. The symptoms do not differ from those of a gastroduodenal fistula. Persistent diarrhea and a rapid loss of weight often accompanied by pain and anemia, are usually present and the occurrence of fecal vomiting is common. The second portion of the duodenum was involved in 7 of the 8 cases; the first portion in 1 case. In 2 of the cases involvement of the duodenum took the form of a duodenocolic fistula. Duodenocolic fistula secondary to malignant disease of the colon is a rare entity and occurs only when the disease is advanced.

The lesions were removed in one or two stages. In 7 of the 8 cases right hemicolectomy with local excision of a portion of the duodenal wall and duodenoplasty was carried out. In the remaining case segmental resection of the colon with partial gastrectomy and partial duodenectomy was done.

The risk of operation in these cases is high. There were 3 deaths in the hospital among the 8 cases. The prognosis in such cases is unfavorable. In the present series the longest survival period following operation was 1 year.

Rosser, C. and Kerr, J. G.: Pilonidal Disease. *J Am Med Ass* 1947 133 1003.

Prior to the recent war the preponderance of surgical opinion was in favor of the so-called open operation for the treatment of pilonidal disease. In contrast practically all the reports by medical officers of their experience while in service favor and advocate some attempt at closure. The latter recommendations appear to be about equally divided between methods of partial closure and complete primary suturing of the wound. The author points out that military conditions require a method of treatment that rehabilitates and returns a soldier to duty as quickly as possible since there is little space available for prolonged hospitalization and no provision for extended convalescence. In civilian practice most patients are allowed to resume their usual activities within 2 weeks after block excision and open packing whereas a soldier with an unhealed wound must be a hospital patient.

To supplement the published literature on this subject and to obtain the opinion of a group of proctologists whose work before the war included surgical experience in the management of pilonidal disease capable of serving as a basis of comparison with their own military observation, a questionnaire was addressed to 35 rectal surgeons who served in World War II. A brief expression was requested on

present opinion in regard to the open or closed type of procedure in civilian practice together with any preference for a special technique in either case. Nonmilitary conditions were specified in the questionnaire because of the different necessities of civilian and military practice with respect to the period of hospitalization and the return to duty.

Twenty seven answers were received and 21 of those who replied (77.7%) now regard the open type of operation as the best standard procedure under the conditions stipulated. Five (18.5%) believe that various closed procedures which were developed in military service will be routinely satisfactory in private practice. Some proctologists set up exacting criteria for the use of the closed procedure. Others who favor open procedures for the majority of cases have become convinced that under certain specified conditions the wound may well be closed at the time of operative intervention. A surprisingly large number of answers expressed satisfaction with the open procedure by which the lesion is marsupialized.

Fair consideration of the studies made by military surgeons indicates that there will be a place in civilian practice for marsupialization and for the reconstructive primary closure of pilonidal wounds when properly indicated and properly performed.

JOHN L. LINDQUIST, M.D.

Rietti, F.: Transitory Icteroascitic Syndrome following Sclerosant Treatment for Hemorrhoids (Sindrome ittero-ascitica transitoria inforta dopo cura sclerosante delle emorroidi). *Arch ital mal app dig* 1947 13 65.

A forty two year old male underwent treatment for external hemorrhoids, consisting of the injection of a 5 per cent solution of quinine hydrochloride and urea. Two weeks after the conclusion of treatment, the patient developed jaundice with claycolored stools and bile pigment in the urine. Although anorexia and asthenia were marked there was no elevation of temperature. The appearance of ascites led to paracentesis which showed a straw colored fluid without evidence of protein. Generalized pruritus was present and sinus bradycardia was noted by the consultant. The clinical picture subsequently improved and the patient appeared to have recovered.

The author supplies a cursory review of opinions on the icteroascitic syndrome and proposes three hypotheses: (1) there is no relation between the injection treatments and the liver disturbance; (2) there is a hypersensitive reaction to quinine which involves the liver; and (3) there is an establishment of a thrombophlebitic process proceeding from the inferior vena cava to the portal vein. The absence of laboratory studies makes a definitive diagnosis difficult, but the third theory is favored by the author.

Although recovery seemed to be complete the patient was to be watched for evidence of hepatic cirrhosis.

EDITH B. FARMWORTH, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Pettinari V.: Contributions to Hepatic Surgery (Contributi di chirurgia epatica) *Minerva med.*, T 1947 38 134.

Seven cases of surgery of the liver are reported.

The series comprises 2 instances of solitary adenoma, 2 of echinococcus cysts and 1 instance each of primary carcinoma involving excision of the entire left lobe, solitary cyst and melanotic tumor with secondary hemorrhage.

Resections of varying portions of the liver were done in all 7 cases with complete return to health in 5. Therefore it is stressed that hepatic surgery is not as formidable as is generally believed and that with good preparation and accurate surgical technique such interventions may be undertaken with out undue risk.

It is to be hoped that diagnostic means may be found by which certain lesions of the liver may be identified and given timely surgical treatment.

EDITH B. FARNWORTH M.D.

Brewer A. A.: Cholecystography A Comparative Study of Oral and Intravenous Contrast Substances. *Radiology* 947 48 269.

For the past 20 years cholecystography with tetraiodophenolphthalein was accepted as the best procedure for the examination of the gall bladder and the intravenous method was considered superior to the oral method.

The more recent introduction of priodax, however soon created the impression that this new dye is an excellent oral contrast medium having definite advantages over the tetraiodophenolphthalein. The author in the present study publishes the results of oral cholecystography with priodax in a series of 50 patients, 46 of whom were also subjected to intravenous cholecystography with sodium tetraiodophenolphthalein for the purpose of comparison.

A proper technique is essential. By the oral method, 6 priodax tablets of 0.6 mgm. are swallowed whole during the course of a fat free evening meal and the first roentgenogram is made the next morning (15 hours later) on an empty stomach. In the intravenous method, 3.5 mgm. of sodium tetraiodophenolphthalein, after being dissolved, properly filtered, and sterilized, is diluted in 500 c.c. of normal saline solution and injected slowly (in 45 minutes) to obviate too much reaction. Roentgenograms are made 4, 8, and 24 hours later.

In 104 patients the gall bladder appeared normal with the oral method of priodax. In 46 patients it appeared to be abnormal and therefore this group was re-examined with the intravenous sodium tetraiodophenolphthalein. In 39 instances the 2 examinations were in perfect accord, while in 7 there was definite disagreement.

In looking for the cause of disagreement the author found that all 7 patients had eaten no fat food or no food at all, prior to the examination. The priodax

given orally led to a faint shadow of the gall bladder indicating poor concentration of the dye but the intravenous method with sodium tetraiodophenolphthalein elicited fairly good to normal density of the gall bladder shadow. From this the author concludes that the gall bladder probably was full of thick concentrated bile which prevented the entrance of the fresh dye laden bile.

In 1935 Jenkinson recommended that all patients with nonvisualization of the gall bladder be placed on a diet rich in fats and re-examined after a month. It seems that such a procedure has a very definite advantage since it cleanses the gall bladder of the stagnating thick bile. Therefore one may assume that in the presence of a gall bladder with faint filling the accuracy of the diagnosis may be improved by repeating the examination with intravenous cholecystography preceded by a high fat diet.

T. LITVIN, M.D.

Calzolari T., and Dorfman, G. E.: Calcareous Cholelithiasis Stimulating a Porcelain Gall Bladder (Calcereas cholelithiasis stimulans una cholelithiasis porcellanea) *Polidolusica sex. chir.* 947 54 36.

A single case of biliary calculus is reported, in which the large calculus was of pure calcium carbonate while the lesser calculus was composed of a nucleus of cholesterol surrounded by calcium carbonate. Because of the unusual volume of the gall bladder the form suggested by the first type of stone, and the peculiar configuration of the second stone a false roentgenographic interpretation of total calcification of the wall of the gall bladder was made.

The largest stone was 50 mm. in length, 30 mm. in diameter and weighed 11.5 gm. while the smaller stone was 12 mm. in length 6 mm. in its greatest diameter and weighed 70 centigrams.

Calcium carbonate stones may be divided into two types (1) small stones which are of hard consistency and (2) larger stones which are less hard or even of soft consistency. The calcium may be derived from bile or exudate rich in calcium. While the pathogenesis is dependent on obstruction of the cystic duct stasis of bile and infection of the gall bladder the main factors responsible for the production of any one specific type of stone are (1) the special degree of virulence of the bacteria, and (2) the special infection of the gall bladder.

ANTHONY F. CIRIO, M.D.

Hultborn, E. A.: On Spontaneous Complete Discharge of Stones from the Gall Bladder and Common Duct. *Acta chir. scand.* 947 95 260.

The author describes 3 unusual cases in which stones in the gall bladder and bile ducts were believed to have passed spontaneously.

The first case was that of a young woman who had 5 typical attacks of gallstone colic. Cholecystography established the presence of a large number of pepper corn sized nonroentgenopaque stones present in the gall bladder. At operation 2 months after the last examination no concretions could be detected.

Two additional cases were presented in which intestinal cholecystography revealed several small stones that subsequently disappeared upon repeated x ray examinations. In all 3 cases the stones were of a very small size.

In view of the possibility that gallstones if they are sufficiently small may pass into the duodenum spontaneously the writer suggests that it may be advisable to use choleretics cholecytokinetics and spasmolytics to improve the prospect for the spontaneous passage of concretions. Bile salts stimulate bile secretion, and olive oil and egg yolk produce the sphincter of Oddi and small doses of magnesium sulfate favor the evacuation of the gall bladder. If spontaneous passage of small gallstones may evidently occur then repeated cholecystography is advisable if some time has elapsed between the x ray examination and the intended operation.

The author considers it quite unlikely that the unusual disappearance of gallstones is the result of their spontaneous dissolution. He prefers to believe that small stones may pass by natural processes from the gall bladder through the biliary ducts into the duodenum.

Edward F. Lewison M.D.
 Gaertner E.J. Cystic Dilatation of the Common Duct. *Endocholedochorrhaphy. Cure (Dilatation of the ducts do colédoque endocholedochorrhaphy. Cure)*
Rev. Brasil Cir. 1947 16 65

A cystic dilatation of the common duct was observed by the author in a 14 year old boy with complaints of a year's duration. A tumor in the right upper quadrant of the abdomen was changing its size from time to time. Frequent attacks of nausea and vomiting were recorded in the history. The percussion sound over the tumor was sonorous.

A tentative diagnosis of cyst of the liver or the mesentery was made but the exploration revealed a large retroperitoneal fluctuating tumor. The abdomen was closed on the assumption that a gigantic right hydronephrosis was present. Excretory urograms did not confirm the diagnosis and the patient was again operated upon 5 months after the first intervention. A cyst of the common duct containing 1500 c.c. of bile was found. A probe introduced through the lumen of the cyst reached the duodenum. The posterolateral approach employed for the operation would offer technical difficulties to cholecystectomy and therefore the author chose a method of reconstruction of fusiform aneurysms. The postoperative course was uneventful and was not complicated by vomiting or any other digestive disturbance.

The etiology of a cystic dilatation of the common duct remains obscure but several factors may be considered viz congenital malformation trauma or compression by a pregnant uterus, adenoma of the pancreas, and tuberculous infiltration of the mesentery. A cystic dilatation of the duct should not be confused with a diffuse dilatation of the duct which

follows an obstruction by a gallstone dystony of the sphincter or compression by a tumor. The condition may become complicated by an infection of the biliary system.

Tumefaction and pains are the main symptoms while jaundice is rare. As to the treatment external drainage or marsupialization should be avoided. Endocholedochorrhaphy is preferable to cholecystoduodenostomy because it preserves a normally functioning gall bladder.

Cole W.H. Suppurative Cholangitis. *Surg. Clin. N. America* 1947 37 35

In most cases suppurative cholangitis probably starts in the extrahepatic bile ducts and tends to proceed upward into the liver particularly if there is obstruction to the flow of bile. It rarely occurs when there is no obstruction. The most common bacteria producing the infection are the *Escherichia coli* the *Streptococcus* and the *Staphylococcus*. The infection is usually of a mixed type although cultures taken at various intervals may not reveal all three of these bacteria at the same time.

Stone in the common duct is the most common type of obstruction giving rise to suppurative cholangitis and is the one type which may clear spontaneously because of the ball valve action of the stone. The obstruction due to stone is not as complete and persistent as most other obstructions. Carcinoma of the pancreas is not recognized as being a common cause of suppurative cholangitis but the author has seen several cases in which this lesion was the etiologic factor. Stricture of the common duct almost always gives rise to suppurative cholangitis sooner or later. Usually stricture is secondary to trauma sustained at operation on the biliary tract. In a few instances it appears that there is an unusual type of inflammatory reaction which might be designated as obliterative cholangitis which can produce serious obstruction. It is possible that on some occasions an abscess may develop postoperatively about the duct thus giving rise to inflammation in the wall. Congenital cystic dilatation of the common duct may give rise to suppurative cholangitis but not frequently because no antecedent infection exists. Regurgitation of the intestinal contents into the common duct or intrahepatic bile ducts can give rise to suppurative cholangitis. Infection will develop much more commonly in the presence of regurgitation if there is partial obstruction, although the author describes 3 cases in which suppurative cholangitis was produced by regurgitation in the absence of duct obstruction. Suppurative cholangitis is much less likely to develop if there is an appreciable amount of common duct although proof in the liver and the source of regurgitation in the intestine. The initial source of the infection is probably in the wall of the common duct although proof in the section may more readily be obtained from the presence of purulent material in the lumen of the common duct. Ascending infection through the sphincter

ter of Oddi up the common duct can be excluded as a significant factor in the development of infection. After infection once develops in the wall of the common duct it tends to spread to the contents of the lumen and to progress upward into the liver particularly if there is obstruction to the flow of bile. The wall of the common duct becomes thickened, edematous, and fibrosed. When the infection extends into the liver there is a tendency for the development of multiple liver abscesses. The contents of the common bile duct may or may not be frankly purulent. The presence of white bile indicates obstruction but in itself no indication of the presence of infection. The bile retains a rather transparent glairy appearance until it is infected after infection develops it becomes opaque, loses its opalescent appearance, and becomes thicker.

The clinical manifestations are

1. Chills and fever. The chills vary greatly in frequency and fever without chills is frequently present.

2. Jaundice and acholic stools. Since obstruction is usually present jaundice is fairly constant. Jaundice may not be demonstrable at the time of the first symptoms of chills and fever. The stool may be acholic before jaundice is demonstrable in the skin. If the stool has a normal color it may suggest that the obstruction is only partial or that it is intermittent.

3. Pain. The presence or absence of pain depends on the type of lesion producing the obstruction or infection. With very few exceptions the patient will complain of pain if the infection is secondary to stone in the common duct. If the infection is produced by stricture, pain is variable and, although usually present it is usually of less intensity. When the condition is caused by carcinoma of the head of the pancreas, pain is not commonly encountered.

4. Nausea and vomiting. During the attacks of chills and fever these symptoms are common, but they are uncommon between attacks.

5. Weakness and prostration. During the acute attack weakness is pronounced. If jaundice and fever persist beyond the acute attack, weakness will be still more pronounced.

6. Positive physical findings. Enlargement of the liver and mild tenderness in the right upper quadrant are present in the majority of cases but muscle spasm is uncommon. The diaphragm may be elevated on the right. Tachycardia is fairly pronounced the degree being dependent on the amount of fever.

7. The most pronounced positive laboratory finding is leucocytosis, usually of marked degree. Anemia is common. Examination of the urine and stool for bile is usually positive and negative respectively.

Surgical drainage of the common duct is essential in the treatment of suppurative cholangitis. Penicillin cannot be relied on as the sole form of treatment, although it should be given and continued for several days after drainage is established. Streptomycin will probably prove to be much more effective than penicillin. If culture of the bile obtained by choledochos-

tomy reveals the *Escherichia coli*, streptomycin is indicated in preference to penicillin. Sulfonamides are helpful but not as effective as these two drugs. Preoperative and postoperative care is stressed, and particular attention should be given to fluid and electrolyte imbalance and anemia. Drainage of the common duct with a T-tube is necessary and attempts should be made to correct the obstruction, particularly if it is due to a stone in the common duct. If the patient is extremely sick, confirmation of patency of the lower end of the common duct by time consuming manipulations will not usually be necessary or justifiable. If an obstruction is present it can be corrected later.

Five cases of suppurative cholangitis due to various causes are described. Because regurgitation of food through the choledochointerostomy opening occurs following anastomosis of a loop of jejunum to the hilar duct, the author no longer employs this procedure but uses a single arm of jejunum for the anastomosis, after the principle of Roux.

JOHN L. LINDGREN, M.D.

MISCELLANEOUS

Thorek, P. The 6 Subphrenic Spaces. *Surgery*, 1947, 73:9.

If subphrenic disease be kept in mind, especially as a complication of intra-abdominal suppurative processes, it can be diagnosed earlier and treated more effectively.

The subphrenic space is that which exists between the diaphragm above and the transverse colon and its mesocolon below. This area is divided by the E into suprahepatic and infrahepatic portions. The suprahepatic part is bounded above by the diaphragm and below by the upper surface of the liver. The infrahepatic part is bounded above by the under surface of the liver and below by the transverse colon and its mesocolon. Three suprahepatic and three infrahepatic spaces exist. The falciform ligament divides the suprahepatic area into right and left parts. The superior surface of the right lobe of the liver resembles an inverted cup or bowl, so that this surface appears both anteriorly and posteriorly. The cut section of the left lobe however resembles a chip so that the dome shaped anterior and posterior relations of the superior surface are wanting. On the right side, the right lateral ligament which is a prolongation of the coronary ligament, divides this area into two spaces, a large anterior and a small posterior one. These ligaments are peritoneal reflections. The left lateral ligament passes along the posterior border of the left lobe of the liver and separates the superior from the inferior surface. Therefore only one space exists to the left of the falciform ligament. The three suprahepatic spaces then constructed are named in the following way: space 1 which exists above the liver anterior to the right lateral ligament and 2 the right of the falciform ligament and is also called the right superior anterior subphrenic space; space 3 which is located to the right of the falciform ligament, takes in the

superior surface of the liver and is behind the right lateral ligament and is also called the right superior posterior subphrenic space and space 3 which is situated between the liver and the left half of the diaphragm, and is also known as the left superior subphrenic space. The infrahepatic area is divided into right and left parts by the descending portion of the duodenum although some anatomists use the ductus venosus for this division. The right inferior subphrenic space is located to the right of the duodenum and below the liver and is the same as the hepatorenocolic pouch of Morrison. The left side of the infrahepatic space is divided by the stomach into anterior and posterior parts. This creates a space which exists to the left of the duodenum and in front of the stomach and hence is named the left inferior anterior subphrenic space. This also has been referred to as the perigastric space. The final or sixth space is situated to the left of the duodenum, below the liver but behind the stomach. It is known as the left inferior posterior space or the lesser peritoneal cavity (omental bursa). All of the spaces are intra-peritoneal.

The space most frequently involved is the one which is the smallest and most difficult to reach namely the right superior posterior. This is due to the fact that the most frequent causes of subphrenic infection are on the right side namely acute appendicitis, acute cholecystitis, and perforated peptic ulcer. An inflammatory exudate from any of these three lesions may travel upward along the so-called paracolic groove of the ascending colon and localize in this space which is the most difficult to reach surgically and causes the most difficulty in diagnosis.

The diagnosis of subphrenic abscess can usually be made if the condition is kept in mind. The inaccessibility of the subphrenic region also accounts for the delay in diagnosis but there are many signs and symptoms which will suggest the possibility of this lesion. The onset may be abrupt or insidious, but the one outstanding finding is continuous fever. An unexplained fever which persists following a suppurative intraperitoneal process should at least suggest subphrenic abscess. The patient complains of pain or a sense of pressure in the upper abdomen or loin which is usually aggravated by deep inspiration and thus may be confused with pleurisy or pneumonia. If an infection is present in the right posterior superior space, the pain may be referred to the lumbar region however the cases which involve the right anterior superior space or right inferior space usually have pain which is referred to the right costal margin.

Localized tenderness which is found over the involved region is of greatest diagnostic importance however its absence does not rule out subphrenic pathology. If an abscess is present in the right posterior superior space the tenderness localizes over the right twelfth rib. By the same token local tenderness is found along the costal margin on the respective sides. In abscesses in the right anterior superior the right inferior the left superior and the left anterior inferior spaces. The liver is displaced down

Fig. 1 (Thorek) a. The three suprahepatic spaces. The suprahepatic region is divided by the falciform ligament into right and left parts. Space No. 1 is situated to the right of the falciform ligament, above the liver and anterior to the right lateral ligament. It is therefore called the right superior anterior space. Space No. 2 is located to the right of the falciform ligament, above the liver and behind the right lateral ligament. It is called the right superior posterior space. Spaces Nos. 1 and 2 are separated from each other posteriorly by the bare area of the liver. Space No. 3 is found to the left of the falciform ligament and, since the left lateral ligament passes posteriorly along the flattened left lobe of the liver, there is only one space on this side in contrast to the two on the right. It is called the left superior space. b. The three infrahepatic spaces. The infrahepatic region is divided by the descending duodenum into right and left parts. For convenience these spaces have been numbered 4, 5, and 6. Space No. 4 is to the right of the duodenum, and below the liver. It is therefore called the right inferior space. This is the same as the hepatorenocolic pouch of Morrison. Space No. 5 is found to the left of the duodenum, below the liver and in front of the stomach. It is called the left inferior anterior space. Space No. 6 is located to the left of the duodenum, below the liver and behind the stomach. It is called the left inferior posterior space or lesser peritoneal cavity. The arrow indicates its position and surgical approach.

ward and an area of increased liver dullness to percussion will be found in abscesses of the right anterior superior the right posterior superior and the left superior spaces.

Roentgenography is of great help if one emphasizes the importance of the fluoroscope instead of the x ray plate. Although it is true that the diaphragm is elevated in subphrenic abscess, this in itself is not pathognomonic. On the other hand immobility of the hemidiaphragm on the involved side is most suggestive of subphrenic pathology this sign is of utmost importance and is most essential to the diagnosis. The presence of gas represents a late finding hence a neglected case however its absence denoting a more favorable condition, does not eliminate the diagnosis of subphrenic abscess.

The use of aspiration for diagnosis is feared because of the danger of contaminating the pleural or peritoneal cavities.

Treatment is dependent upon the location of the infection and the presence or absence of suppuration. Since the majority of subphrenic infections do not go on to suppuration they may be treated by conservative measures, especially by modern chemotherapy

If the white blood count rises above 20,000, it is most suggestive of a suppurative process which will necessitate surgical intervention and drainage. It is of utmost importance to avoid contamination of uninvolved cavities in the drainage of such an abscess. This is imperative when the pleural and peritoneal cavities are concerned since the marked absorptibility of serous membranes might produce an immediate overwhelming toxemia. The ideal procedure, surgical approach is an extraperitoneal one in which the abscess is approached either from in front or from behind, according to the location of the abscess. Since the right superior posterior space is the one most frequently involved a retroperitoneal operation is usually performed. The only point which bears emphasis is based upon the work of Medakoff who showed the variations and the relation of the costophrenic angle to the twelfth rib. This point is that the skin incision is made along the course of the twelfth rib but the incision through the rib bed should change its course to a transverse one. The latter is made at the level of the spinous process of the first lumbar vertebra to avoid contamination of the pleural cavity.

BENJAMIN GOLDBACK, M.D.

GYNECOLOGY

UTERUS

De Queiroz, A.P. Review of 540 Cases of Genital Prolapse Observed at the Gynecologic Clinic of the Bahia School of Medicine Since Its Creation until the Present Times 1911-1946 (Revisão de 540 casos de prolapso genital observados na Clínica Ginecológica da Faculdade de Medicina da Bahia desde a sua criação Até hoje 1911-1946) *Am. brasíl. gín.* 1946 11: 435

During the 35 year period from 1911 to 1946 540 patients, or 10.5 per cent of the entire material (5143 patients) observed at the Gynecologic Clinic of the Bahia School of Medicine, presented genital prolapse. Sixty per cent had complete procidentia and 40 per cent, partial prolapse or so-called descensus. The incidence of the colored patients, the greatest being that among the colored patients, between 30 and 40 years of age. In 24 cases a concomitant lymphopadnia venerea was present. Among the 540 patients 10 were virgins and 19 were nulliparas. The condition occurred with the greatest frequency in multiparas with two pregnancies.

Of the great variety of operative procedures the author favors Ponsi's hysterocoelectomy and Bouill's operation or the colpoepineal plastic operation with cervical amputation. JOSEPH K. NAKAT, M.D.

Boveas J. L. Functional Surgery in Uterine Myomas (La cirugía funcional en el mioma uterino) *Rev. méd. Rosario* 1946 39: 784 1947 37: 39.

In the gynecologic section of the author's hospital up to the present there have been 1453 surgical interventions on the uterus. In this material there were 358 postoperative complications. These included 100 (74.1 per cent) in 147 total hysterectomies, 100 (11.1 per cent) in 893 subtotal hysterectomies and 68 (78.4 per cent) in 88 vaginal hysterectomies. The complications included 31 cases of bronchopneumonia (3 in the myomectomies), 13 parotitis (15 of operative shock (15 with fever of unknown origin and 4 in the cardiac collapse (3 cases of paralytic ileus, 11 cases of acidosis and among the myomectomies), 11 cases of peripheral collapse, 6 of cardiac insufficiency, 13 of acidosis and the remainder a variety of complications of lesser importance. The general mortality for this material is not discussed other than to mention that the mortality on the whole corresponded in incidence to the complications. Among the myomectomies there were 4 deaths. One of these deaths was the result of bronchopneumonia, 1 of cardiovascular collapse, 1 of embolism and 1 of pneumonia. The results obtained in these myomectomies are not discussed in detail since they have been reported by the author's associate, Bórras, in numerous articles. The author merely states in a general way that the immediate results in these patients have

been satisfactory both from the psychic and physical aspects. The menstrual flow during the first 6 months following the operation has been rather abundant lasting from 6 to 8 days but amenable on the whole to the usual methods of therapeutics. Of the 213 myomectomized women in the last 6 years the 213 have become pregnant. Of these 2 had previously been sterile, and some of them had been married but without children for as long as 14 years. Ten of these 15 patients delivered normally, 2 were delivered by cesarean operation. In these 2 there had not been any sign of a tendency toward labor which led to the suspicion that the uterus had lost the proper disposition of its nerves and muscular structure for the initiation of labor. Three of the myomectomies were carried out during pregnancy and the 2 others terminated in spontaneous abortion and the 2 others went on to normal delivery.

The author believes that part of their excellent results are to be ascribed to Bórras' method of pre-cautionary hemostasis which is illustrated in the original article.

The myometrectomy of Cino which was described by Cino himself 3 years ago (*Obst. gín. lat. amer. B. Ar.* 1945 3: 761) and abstracted in the INTERNATIONAL ABSTRACTS of SURGERY (1946 83: 52) is also illustrated but no mention is made of any experience therewith. JOHN W. BROWN, M.D.

Heyman J. The Radiotherapeutic Treatment of Cancer Corporis Uteri. *Brit. J. Radiol.* 1947 30: 85

Of 100 cases of cancer of the uterus referred to the Radiumhemmet for treatment, between 20 to 25 are cancer of the corpus. Hysterectomy is definitely not applicable to 80 per cent of the cases. It is true that the great majority of corpus cancers are bad as far as the anatomic extent of the growth is concerned. However many of these cases are bad operative risks because of old age, adiposity, heart conditions and similar complicating diseases. Of 670 cases observed during the period from 1914 to 1939, inclusive, but clinically inoperable cases, 1039, operative but clinically inoperable cases amounted to more than 50 per cent of the total.

The 5 year cure rate obtained by hysterectomy in cancer of the corpus is difficult to estimate. The relative 5 year cure rate in 4 reports involving series of five 5 year cure rate in 4 reports involving series of 100 or more varies between 48 and 55 per cent. At the Radiumhemmet a combined operative and radiotherapeutic treatment has been adopted in this treatment radiotherapy plays the primary and most important part. Since 1930 a radiotherapeutic technique which is now used as a routine in the treatment of corpus cancer has gradually been elaborated. It involves packing the uterus with a sufficient number of radium containers to get the uterine cavity completely filled.

In packing, either tubes containing 8 mgm. of radium element or needles containing 10 mgm. of radium element, the filter of the wall being equivalent to 1 mm. of lead are used. Each tube or needle is placed in an additional filter the size of which varies according to the width of the uterine cavity small filters being applied to small cavities and large filters to large cavities. Additional filters of 6 different sizes each with a wall thickness equivalent to 3 mm. of lead, are used. The variation of the diameter of the additional filter is achieved by varying the air space between its external and internal wall. The irradiator ready for use consists of the tube the additional filter and a screw plug which fits all the filters and to which is attached the tube holder for insertion of the tube. For introducing the irradiators into the uterus a special applicator is used. One end of the applicator fits the screw plug at the other end is a wedge and a clamping plate for securing the string during introduction. The technical skill required for application is not difficult to acquire. Accidents have been rare. In the total series of cases, at present amounting to about 1000, serious accidents have occurred 3 times all of them were due to perforation of the uterus. The irradiators are removed by the nurse and generally without any difficulty.

In most cases of corpus cancer at the Radium hemimet radiotherapy is the primary therapeutic interference. Two treatments are given with an interval of 3 weeks. In of the treatments radium is also applied to the vagina in order to prevent vaginal metastases. Roentgen treatment is administered in such cases only when fixation of the uterus indicates that the growth has spread to adjacent organs.

Surgical interference is resorted to in case of failure of radiotherapy which is indicated usually by repeated bleeding or increase in size of the uterus. There is no difficulty in removing the uterus after a properly conducted radium treatment. Even a subtotal hysterectomy will suffice in many of the recurrent cases and may be helpful in cases difficult to operate upon for one reason or another. Surgery may occasionally be resorted to as a primary interference, for instance in cases of corpus cancer combined with large fibroids.

The irradiators remain in the uterus for a varying length of time, according to the amount of radium applied and to the type of irradiator used. On the

basis of previous empirical experience the dose of 1500 element hours, given twice at 3 week intervals has been adopted as the most suitable one when 10 irradiators each containing a tube of 8 mgm of radium element and with an additional filter of medium size are used.

At each treatment the patient remains for 4 or 5 days in the hospital.

The results are given in Table 1:

For the 205 patients treated in the period from 1934 to 1939, the relative cure rate is 64.9%.

The results in different groups were as follows: clinically operable, 67 per cent, 5 year cures technically operable 48 per cent cures and inoperable, 28.7 per cent cures. DUMAS, G. MORRIS, M.D.

Lipin T., and Davison, G.: Metastases of Uterine Carcinoma to the Central Nervous System: A Clinicopathologic Study. *Arch. New York*, Phila. 947 57 86.

The author notes that metastases of carcinoma of the uterus to the central nervous system are infrequent. These metastases are often solitary and may occur in the absence of widespread disease. In cases of a single metastatic nodule in the brain without evidence of carcinomatosis, the advisability of neurosurgical intervention should be considered, for in selected cases life may be prolonged appreciably by operation.

Three cases of metastatic brain tumor from uterine cancer are reported in detail in all of which the primary growth was adenocarcinoma of the fundus. In addition 3 cases of metastatic tumor of the brain from carcinoma of the uterus are summarized from the literature because they illustrate important points. The first case presented by the author illustrates that carcinoma of the uterus may give rise to a solitary metastasis to the brain in the absence of metastases to other organs. The second case reveals that evidence of carcinomatosis appeared 5 years after the patient had a hysterectomy for a uterine adenocarcinoma. Although there were multiple metastases to many organs, only a single metastatic nodule was observed in the brain. In the third case a single metastasis to the central nervous system occurred in a patient with carcinomatosis secondary to a malignant growth in the uterine fundus.

In a discussion of therapy the author notes that neurosurgical intervention is contraindicated in most cases of metastatic tumor of the brain secondary to uterine carcinoma because of the frequent accompaniment of carcinomatosis but when there is not evidence of this complication and when signs suggest a solitary brain tumor neurosurgical intervention may prolong life.

In conclusion the author notes that metastases from carcinoma of the uterus probably account for 1 to 3 per cent of all carcinomas of the central nervous system. The percentage of uterine carcinomas metastasizing to the central nervous system varies from 0.1 to 3.4 per cent according to different sources.

TABLE 1—THE 5 YEAR RESULTS IN CASES TREATED FROM 1914 TO 1939 INCLUSIVE

Total number of patients examined	698
No. of patients alive without evidence of the disease	363
Absolute cure rate	52.0%
Number of patients treated	670
No. of patients alive without evidence of the disease	363
Relative cure rate	54.0%

Carcinoma of the breast, lung, pharynx, sinuses, thyroid, and adrenal glands may metastasize more frequently to the central nervous system than carcinoma of the uterus, whereas carcinoma of the stomach, urinary bladder, pancreas, and esophagus may metastasize less frequently. There is evidence that metastases to the central nervous system from uterine carcinoma are often solitary.

Uterine carcinoma may metastasize to the central nervous system in the absence of carcinomatosis. In cases in which metastasis to the central nervous system from a carcinoma of the uterus is suspected, neurosurgical exploration is indicated only if there is no evidence of multiple metastases to the brain or spinal cord and no evidence of carcinomatosis.

HERBERT F. THURSTON, M.D.

Ahlborg G. On Conservative Myomectomy. *Acta Obst. Gyn. Scand.* 1946 16 Supp. 6

The author presents an exhaustive study on the subject of myomectomy; the first 78 pages of which are devoted to a survey of the literature. He has felt justified in subjecting the views expressed in these monographs to a detailed and rigid scrutiny, since he believes, from previous studies, that no conclusive proof of the relative advantages and disadvantages of myomectomy has so far been adduced. Statistics in Sweden for the years 1925, 1930, 1935, and 1940 reveal an increase in the relative frequency of myomectomy in the special clinics and operations of this kind were commoner in the special clinics than in the local hospitals.

A detailed description is given of the method of enucleation employed. At the conclusion of the operation it is customary to insure ventral fixation of the uterus seroserosally against the anterior abdominal wall. In the author's series, 18 of the patients who had undergone ventral fixation later became gravid. In 14 instances pregnancy proceeded to term; miscarriages occurred in 4 cases.

The author's material comprises 382 abdominal myomectomies and 46 vaginal myomectomies and 92 per cent of the patients were operated upon by the same surgeon.

Multiple fibroids occurred in 69 per cent of the patients. In the majority of cases solitary fibroids were treated by enucleation, while multiple fibroids were treated by radical operation. The greatest number of tumors removed in a single case was 30. Solitary fibroids were commoner in patients who had previously undergone a pregnancy, while multiple fibroids were found more frequently in sterile patients.

The majority of patients treated by enucleation were young; the reverse was true of those who were treated by radical operation. Menorrhagia, pains, and sterility, in the order named, were the most frequent indications for operation. The sizes of the enucleated fibroids varied within wide limits. There seemed to be no relation between the size and the number of fibroids, between the size of the fibroids and a preceding pregnancy, the size of the fibroids

and the age of the patient at operation, nor between the size of such tumors and their position in the uterus.

Necrosis occurred in 20 per cent of the cases and was more common among gravid patients. This did not constitute a contraindication to enucleation. The sedimentation reaction provided no certain clue as to the presence of necrosis.

Adenomyomas occurred in 5 per cent of the patients treated by enucleation. Not a single instance of sarcoma was discovered among the patients in whom abdominal myomectomy was performed. In 3 cases cellular leiomyomas were diagnosed. A diagnosis of sarcoma was made in 1 of the 46 cases in which vaginal myomectomy was performed. Of the 573 patients who had undergone radical operation for fibroids, a postoperative diagnosis of sarcoma was made in 2 cases. If all cases are included, the incidence of sarcoma in 902 cases of fibroids is 0.55 per cent. In not one of the cases in which enucleation was considered was it necessary to abandon this method of treatment because of coexistent cancer in the uterus, although cancer was found in 1 case in which radical operation had been performed.

Although the uterine cavity was usually left unopened during enucleation, it was explored in 16 per cent of the cases. It is believed that exploration of the uterine cavity may be justified in certain cases.

Excision of the myoma capsule in myomectomy was carried out only in exceptional cases.

Changes in the adnexa or pelvic peritoneum were registered in 48 per cent of the 382 cases in which enucleation was accomplished, and in 46 per cent of the cases in which radical operation was carried out. It is not rational to limit enucleation strictly to those cases in which the appendages are completely normal.

Complications during enucleation arose in only 3.5 per cent of the cases. The most common complication was hemorrhage during and after enucleation. All patients recovered. Variations of temperature after myomectomy were on the average moderate.

Postoperative involution appeared to be complete after a period of a few months and the uterus was eventually restored to its normal size and shape.

Not a single postoperative death is recorded among the 382 patients subjected to abdominal myomectomy. One reason for this may be that patients subjected to enucleation are usually good subjects for the operation. The death rate attending 573 radical operations was 2 per cent. Any direct comparison between the death rate in the two groups must be misleading, since the radical operation is applicable to older age groups and to more complicated cases than those found in the conservative group.

Two hundred and fifty-five patients (90%) who underwent enucleation showed a postoperative sequence free from all complications. Serious complications arose in only 3 per cent of the cases. Complications associated with healing are believed to be somewhat more common after radical operation than after abdominal myomectomy. The postoperative

sequence does not appear to be unfavorably influenced by the enucleation of necrotic or large fibroids, by exploration of the uterine cavity in the course of enucleation, nor by chronic inflammation of the tubes, and abdominal wound healing is better than that following radical surgery.

Enucleation was performed during pregnancy in 14 cases—before term in 11 patients and in conjunction with cesarean section at term in 3. Of the 11 cases, 6 pregnancies were maintained and 5 were arrested. Partial myomectomies were performed in 8 patients, 7 of whom were pregnant.

Of the 185 patients subjected to enucleation, 15 per cent desired treatment for sterility; however sterility did not constitute the main indication for operation.

A variety of factors determine the suitability or otherwise, of conservative treatment in a given case of fibroids: the age of the patient, the number of fibroids, and their location in the uterus, the delimitation of the tumor from the surrounding myometrium, the condition of the ovaries and tubes, together with the patient's case history and individual preferences in the matter of a radical or conservative procedure. In many instances the final choice cannot be made until the operation is actually in progress.

As a result of re-examination of the patients it was found that of 161 women who had undergone enucleation 75 per cent were free from recurrence; 167 patients (88%) were found to be symptomless and 47 patients complained of various disabilities, the commonest being menorrhagia and dysmenorrhea. The symptoms were alike both in patients with recurrence and in those free from recurrence.

While enucleation sometimes results in a reduction of the quantity and duration of the menstrual flow some patients find that their menorrhagia is unaffected by enucleation and in these it is believed that myomectomy might well be supplemented by curettage of the uterine mucous membrane. About three fourths of the women subjected to myomectomy were found to be free from menstrual pains after operation.

Of the 93 patients subjected to enucleation, who were in condition to conceive after operation, 31 per cent became pregnant. The mothers in question gave birth to 36 living infants and 1 stillborn infant. On the whole these pregnancies followed a normal course. Spontaneous deliveries occurred in 29 of 36 patients. In 5 cases forceps were applied and in 1 case cesarean section was performed. The majority of these patients were old primiparas. All of the mothers survived delivery.

There is no substantial evidence to suggest that pregnancy and labor are especially influenced by the number of fibroids shelled out by their size or by the opening of the uterine cavity in the course of enucleation. The interval between enucleation and conception is often remarkably short. Of 31 intrauterine first pregnancies occurring after enucleation 23 (74%) proceeded to term.

Certain cases of pregnancy helped to clarify the possible influence of uterine fibroids on sterility. In 5 of the patients sterility had persisted for a period of from 3 to 15 years, and these patients became pregnant within a year of the operation. Here, in all probability sterility was cured as a result of myomectomy. Pregnancy developed later in 3 of the 8 patients in whom a salpingostomy had been performed. In only a single instance did pregnancy develop following vaginal myomectomy.

T. FLORIN BRIL, M.D.

ADRENAL AND PERIUTERINE CONDITIONS

Guillemin G. and Mousselon, J.: *Étiologique Investigation into Adrenal Tuberculosis during the War Years. Clinical and Therapeutic Deductions Concerning 80 Recent Observations* (Enquête étiologique sur la tuberculose adrénaïque pendant les années de guerre, déductions cliniques et thérapeutiques. A propos de 80 observations récentes). *Lyon chir.* 947 48 79.

During recent years the authors have noted as alarming increase in adrenal tuberculosis. They attribute this increase to hard living conditions, physical strain and added responsibilities placed upon women as a result of the war and its consequences.

Formerly tuberculosis in the adrenals was a rarity few cases being encountered from year to year. During the 7 year period from 1925 to 1932, inclusive, only 30 cases were observed in the hospital and private clinic of Cotte but during the 6 year period from 1930 to 1935, inclusive, 80 cases were treated in the hospital and 30 cases in the private clinic of Cotte, a total of 110 cases. The condition quadrupled itself in the last named period.

In all of the 80 cases the tuberculous nature of the lesion was proved. In 44 cases there was positive anatomopathologic proof. In 3 cases there was positive bacteriologic proof, the bacillus of Koch being identified in the pus from the lesion or by guinea pig inoculation. In 33 cases, antecedent tuberculosis lesions in other parts of the body and verification of tuberculosis at the time of surgical intervention afforded sufficient proof so that anatomopathologic and bacteriologic proof was superfluous.

Adrenal tuberculosis was found to occur most often in young women. Of the 80 patients, 6 were less than 30 years, 40 were between 30 and 39 years, 21 between 40 and 49 years, and 6 were more than 50 years of age.

A majority of the patients had shown evidence of tuberculosis in other parts of the body before they developed trouble in the adrenals. Twenty-one of the 80 (26%) had shown pleuropulmonary tuberculosis, 3 had had tuberculosis of the pulmonary parenchyma and the remainder had had cervical adenitis or renal tuberculosis.

The disease was found most often in young married women especially those who had borne children. Cases of adrenal tuberculosis are presented by the authors to show that married life and childbirth

played an important part in producing acute adnexitis in young women who had either arrested or latent tuberculosis in other parts of the body.

Married women complaining of sterility showed evidence of an old pleurisy and an apparent secondarily genital tuberculosis responsible for the condition from which they sought relief.

From the clinical viewpoint the symptoms of which the patients complained were varied. Of the 80 patients treated 18 with acute conditions presented signs of antecedent tuberculosis. In 5 the pain and generalized symptoms were severe on account of the presence of a large abscess in the pouch of Douglas and immediate colpotomy with drainage of the abscess was necessary. Examination of the pus thus obtained afforded the demonstration of Koch's bacillus to clinch the diagnosis of tuberculosis of the adnexa.

The 62 chronic cases presented such symptoms as lumbar or pelvic pain without fever (22 cases) dysmenorrhea (15 cases) menstrual irregularities (10 cases) sterility (16 cases) and postoperative appendectomy fistula (1 case). Pain at the menstrual period or pain between the periods was the most constant symptom. The pain had been present over a long period of time, originating in the lower abdomen and radiating to the lumbar and crural regions. Of ten the pain was mistaken for that originating from an acute appendicitis and only when appendectomy was performed was the true nature of the disease recognized.

For the most part the menstrual disorders complained of were metrorrhagia of ovarian origin, varying in intensity. One patient had been amenorrheic for 6 months when the acute symptoms occurred.

Sterility, which resulted from coarctation of the pelvic organs, was usually asymptomatic. Latent tuberculosis was found in these cases.

One patient, 19 years old, married and without antecedent tuberculosis, sought relief from a right iliac fistula following an operation for acute appendicitis, performed 6 months before entry into the hospital. At the time of the operation a large right iliac abscess, an abscess of the right ovary and bilateral pyosalpinx were found.

In general the surgical treatment of these cases was as conservative as possible. All interventions were carried out through an abdominal incision.

Eighteen cases were operated for the relief of acute adnexitis and pelviperitonitis, the bacteriological nature of the disease not being recognized prior to operation. In 2 cases simple laparotomy was done, in 3 cases unilateral castration was done, in 2 cases bilateral castration was done, in 7 cases the uterus with one or both ovaries was preserved, in 2 cases subtotal hysterectomy was done and in 1 case total hysterectomy was done. Of the 18 patients 4 died soon after the operation, while 2 died some months after the operation, a mortality of 30 per cent.

On the basis of their experience the authors advise that in such acute cases surgical intervention

should be delayed and expectant treatment, heliotherapy and improved living conditions until the patients' general condition has improved sufficiently to undergo operative treatment are indicated.

In chronic cases the surgical risk is not so great. Conservative surgery and avoidance of useless mutilations eliminate the disturbing physical and psychological sequelae attendant upon castration. In cases of unilateral involvement, which are rare (only 4 of the 62 chronic cases were unilateral), the chances for obtaining good results are more favorable. The operations performed on these 62 chronic cases were simple laparotomy (16) unilateral castration (4) bilateral castration (2) conservation of the uterus and of one or both ovaries (35) total hysterectomy (1) and repair of the cornua (4). At the time of surgical intervention 20 resections of the presacral nerves and 20 appendectomies were done. These operations were done to eliminate postoperative dysmenorrhea and discomforts due to chronic appendicitis. In other cases peritonization with freeing of the vesical peritoneum was performed; this had the double advantage of fixing the uterus in good position, thereby preventing secondary retroversion and promoting as complete peritonization as possible to cover the raw surfaces of the pelvis.

In the majority of the cases, there was a postoperative gain in weight, disappearance of fever and in cases in which the uterus was retained a more normal menstruation.

Fifty-two of the 80 cases operated were followed up later. One patient in whom the presacral nerves were not resected complained of dysmenorrhea. Two patients remained amenorrheic in spite of the conservative operation.

There were no deaths among the chronic cases. The immediate postoperative results were so good that in some cases the authors regretted not having done a more radical operation.

BLACKWELL MARKHAM, M.D.

Lluis B. and Ibáñez, A. S.: Studies regarding Ovarian Adnexitis (Estudios sobre el ovario adnexitico). *Rev. esp. obst.*, 1946, 3, 1.

The object of the authors' work was to see what effect adnexitis has on the ovaries.

The first manifestation is an alteration of the menstrual cycle caused most likely by some ovarian destruction due to an oophoritis or abscess formation. Changes observed because of inflammation of the adnexa in order of their frequency were dysmenorrhea (77) polymenorrhea (48) hypermenorrhea (43) metrorrhagia (41) menorrhagia (22) amenorrhea (20) and oligomenorrhea (8). These were found in the study of 2,000 patients.

The etiologic factors productive of these changes were predominantly gonorrhea and abortion. Other causes, but of negligible proportion, were puerperal fever, appendicitis, lacerations and prolapse.

Sterility secondary to adnexitis was found to be as high as 36 per cent and 12 per cent of these cases had no other symptom. STEPHEN A. ZIEGLER, M.D.

Douglase, Al: Masculinizing Tumor of the Ovary of the Adrenal Type. *Am J Obst.*, 947 53 190

A case of masculinizing tumor of the ovary is reported. A 48 year old white woman had complained of backache, lower abdominal pain, and vaginal discharge for a period of 7 years. Two years previous to her admission to the hospital she developed a loss of scalp hair, generalized hypertrichosis necessitating daily shaving of her facial beard, and a bass tone to her voice. There was a loss of libido, and intercourse became painful. The menses had ceased at 37 years of age. Examination revealed a slight hypertension, a male facies, alopecia, generalized hypertrichosis, bass voice, and male type of breasts. The hemoglobin was 115 per cent and the erythrocyte count 6.0 million. The leucocyte count was 9000. Pelvic examination showed the clitoris to be greatly hypertrophied, the uterus to be smooth, firm and slightly enlarged, and a definite tumor to be present in the region of the right ovary.

At operation the right ovary was 4 cm. in diameter, smooth, oval, and light yellow in color. A subtotal hysterectomy, bilateral salpingo-oophorectomy, and perineorrhaphy were performed. Near the center of the right ovary was a light brown, firm, fleshy tumor mass 1.4 by 1.2 by 0.8 cm. Sections of this tumor showed strands of adrenal-like cells in an irregular arrangement. There was no acinous or tubule formation.

This patient was followed up for a period of 3 years and has shown a complete reversion to the feminine characteristics. A slight facial hirsutism has persisted. The pelvis is normal. Hormone tests for androgens revealed only a high elevation of the normal female values. The author presents the evidence pro and con as to whether these tumors are of adrenal or ovarian origin and believes that this case is typical of a proliferation of an adrenal rest.

JOHN R. WOLFE, M.D.

Block, E. Primary Carcinoma of the Fallopian Tube. *Acta radiol. Stockh.* 947 18 49

Primary cancer of the fallopian tube is a rare disease. A report from the Radiumhemmet shows that from 1922 to 1945 only 16 such cases were admitted, less than 1 case per year.

Since the Radiumhemmet presents a larger series of cases than any hitherto reported, and since the postoperative radiation therapy has been given according to practically unchanged methods, the publication of this material is justified even if nothing especially new can be expected regarding the pathology and clinical course of cancer of the tube.

According to obtainable information in the literature, 379 cases have been reported since Renaud, in 1847 first described primary cancer of the fallopian tube. In 1932 Numbberger, in his textbook, tabulated the 301 cases which had been published up to that time. In 30 per cent of these cases, the carcinoma was stated to be bilateral. In most of the cases it was impossible to determine whether the growth was primary or secondary. The incidence was greatest

in the age group from 45 to 50, but cases have been reported at such an early age as 18 and at the advanced age of 73.

The etiology of cancer of the tube does not differ from that of cancer in other organs, although the cancer generally starts in the fimbriated end of the tube.

Like carcinoma of the ovaries, the tubal cancer long remains latent. Pain is reported to be the most common symptom.

In the presence of a mass in the adnexa, the sero-sanguineous discharge is pathognomonic of carcinoma of the fallopian tube, provided conditions in the uterus and the vagina are normal.

In cases of tubal cancer, bleeding is not a constant symptom.

The treatment is surgical, namely removal of the adnexa. Some authors have suggested hysterectomy. However, in so doing they have not considered the desirability of retaining the uterus for postoperative radium application.

Of the 16 cases mentioned, only 3 had been treated with radium; the 13 others were treated by roentgen irradiation only.

A brief report is given of the 16 cases treated at the Radiumhemmet. Of these 16 cases, 6 were definitely primary, while the remaining 10 were probably so. However, 16 cases are too small a number for a statistical study.

At the Radiumhemmet the radiological treatment of tubal cancer has followed practically the same principles as that of cancer of the ovary, namely: 1. Intracavitary or vaginal radium application followed by roentgen treatment to 2 anterior and 2 posterior fields. The radium dose has varied in the uterus from 900 to 1500 mgrm. hours and in the vagina from 1800 to 3,000 mgrm. hours. The roentgen dose has varied also. In later years, however, 4 doses of 400 roentgens are administered to each of 4 fields in the first series, followed 3 months later by a second series of 4 doses of 400 roentgens to each field.

Tubal cancer is not a hopeless disease provided that a radical operation is performed early and that radiation therapy is administered in accordance with the aforementioned method.

MISCELLANEOUS

Hilt, K. E., Hesselstine, H. C., and Goldstein, L.: A Study of the Bacterial Flora of the Normal and Pathologic Vagina and Uterus. *Am J Obst.* 947 53 33.

The authors report the results of a study of the bacterial flora of the vagina in 218 patients during pregnancy and following delivery. Sixty-one of the patients were normal prenatal cases, 73 were pregnant women who had trichomoniasis, clinically and as were patients with other types of vaginitis during pregnancy. In addition, uterine cultures were obtained during the puerperium from 50 normal patients and 45 pathological cases.

The flora of normal pregnant women revealed the most frequent members to be aciduric rods diphtheroid rods *Staphylococcus albus*, and fungi. Non-hemolytic and anaerobic streptococci were isolated frequently. Other organisms were seen only occasionally or not at all. There was no difference between cultures obtained during the first half and second half of pregnancy.

In the patients with trichomoniasis there was an increased frequency of aerobic and anaerobic streptococci bacteroids, and a lower percentage of aciduric rods. Moniliasis was common in patients with other types of vaginitis.

The uterine cultures obtained from both normal and febrile postpartum patients were remarkable in their similarity. The authors emphasize that the presence of large numbers of various types of organisms makes it difficult to determine the causative organism in infection and thus the effect of treatment must be judged accordingly. They also point out that the postpartum uterus and vagina may be the portal of entry for a more diffuse infection.

JOHN R. WOLFF M.D.

Schmitz, H. E. and Towne J. E.: Radium and Roentgen Therapy in the Treatment of Menopausal Uterine Bleeding. *Am. J. Obst.* 1947 53 199

The control of functional climacteric uterine bleeding presents a problem in which there is no uniform consensus. In view of the multitude of methods of treatment proposed for benign uterine bleedings it is apparent that each type of treatment has definite indications and limitations which should not overlap one another. The authors report 412 cases observed during the five year period from 1939 to 1943 at the Mercy Hospital, Loyola University Clinic, Chicago in which uterine hemorrhage was the indication for radiation therapy.

One hundred and sixteen (38 per cent) of the patients received roentgen ray treatment and 296 (71 per cent) had radium therapy. The authors prefer the latter since curettage always precedes it and subsequent treatment is rarely needed. The indications for this type of therapy are essentially the symptoms of profuse or irregular vaginal bleeding in the presence of normal pelvic findings. The authors show the excellent results that can be obtained in the treatment of menopausal bleeding by this

simple method of treatment. The dangers are exceedingly small and the complications following treatment are minor.

De Aquino Salles A. and Couri A. A.: Simultaneous Bilateral Ureteroenteroanastomosis according to Davalos Technique in the Treatment of Incurable Vesicovaginal Fistulas (Uretero-entero-anastomose bilateral simultânea pela técnica de Davalos, no tratamento das fistulas véscico-vaginais incuráveis). *Am. bras. gin.* 1946 22 263

Two cases of vesicovaginal fistula treated by a bilateral simultaneous ureteroenteroanastomosis are reported by the authors who believe that possibly their patients were the first on whom this method was employed. The main principle of the operation is the formation of a valve for the protection of the anastomosis and ureters against ascending infection. The method offers the following advantages:

1. The superior and inferior mesenteric arteries remain preserved.
2. Only one incision is made through the sigmoid and in this manner trauma is reduced.
3. The transverse incision across the sigmoid allows the formation of a valve.

Sulfasuxidine administered orally has proved of inestimable value in the preoperative and postoperative care. Briefly the technique is as follows:

The abdomen is opened through a midline incision. The ureters are mobilized and divided. A transverse incision is made through the serosa and muscularis of the sigmoid and is supplemented by a lateral incision. The ends of the ureters are cut on a bevel and sutured to the submucosa without tension. The serosa and muscularis are sutured over the ureters. Mattress sutures through the serosa and muscularis draw the lower edge of the incision over the ureters. The submucosa and mucosa are incised to allow the ends of the ureters to enter the bowel. Finally the edges of the serosa and muscularis are inverted.

Transient anuria, probably resulting from an edema of the distal end of the ureters, was present in both cases on the third postoperative day but it subsided after a short while. The immediate postoperative results were very good. Intravenous urography showed the presence of hydronephrosis shortly after implantation but the condition gradually disappeared.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Chesley L. C., and Annetto J. E.: Pregnancy in the Patient With Hypertensive Diseases. *Am J Obst* 1947 53 372.

The authors' experience with pregnancy in women with hypertensive disease is presented because there are relatively few such studies based upon any considerable series, and in most studies extant there has been a selective factor in that therapeutic abortions have been done in the more severely hypertensive patients.

From 1931 through 1944 there were 318 women at the Margaret Hague Maternity Hospital, Jersey City N. J., in whom the diagnosis of hypertensive disease as defined by the American Committee on Maternal Welfare could be established, and an analysis was made of the 301 pregnancies of these patients.

The gross fetal loss in prior pregnancies was 35 per cent. In the first hypertensive pregnancy 38 per cent and in subsequent pregnancies 40 per cent fetal loss increased with higher initial blood pressure. Second trimester rises in the blood pressure, higher pressures near delivery, decreased renal function (normal in 93% of the pregnancies), proteinuria and superimposed toxemia.

There were 6 immediate maternal mortalities (3%) and 7 late puerperal deaths. Eight deaths were probably associated with the hypertensive disease while 5 were attributable to intercurrent causes. All late puerperal deaths are known to be included since all patients were traced. The authors conclude that while pregnancy very definitely jeopardizes the hypertensive woman the hazards are not great in 3 of 3 cases as two-thirds escape superimposed toxemia.

Nearly 40 per cent of the women showed drops in the blood pressure in midpregnancy, a point of practical importance for diagnosis inasmuch as a diagnosis of pre-eclampsia may be made if the earlier hypertensive pressures are unknown. Also, this factor confuses the interpretation of permanent hypertension apparently left as a sequel of pre-eclampsia.

JOHN R. WOLFE, M.D.

Grasseot J. A Study of the Pathogenesis and Mechanism of the So-Called "Toxic Accidents of Gestation" (Contribution à l'étude de la pathogénie et du mécanisme des accidents dits "toxiques de la gestation"). *Rev f g. obst* 1947 4 350.

Two clinical observations of eclamptic attacks in pregnant women and a series of experimental studies on the guinea pig form the basis for some tentative suggestions concerning the pathogenesis and modus operandi of the eclamptic state. These observations were made before World War II. The data therefrom were compiled by the author while a prisoner and are presented without further documentation or revision.

The first observation was that of a severe case of eclamptic convulsions with deep continuous coma. The convulsive seizures were uncontrolled by alcohol or morphine but the blood pressure of over 200 mm. Hg was practically completely controlled by combined medication with calcium gluconate and hypophosphite of magnesium. The child died during the period of medication.

The other observation was that of a woman with a 5 months' pregnancy who was thrown into a typical eclamptic state with blood pressure of 180-190, convulsive seizures, and coma. The condition was immediately ameliorated as a result of artificial emptying of the uterus, at the end of pregnancy of a living child.

In an attempt to understand the dramatic effects of the combined calcium-magnesium medication and the apparently noxious action of the hypophyseal extract a series of experiments were conducted on guinea pigs. The first experimental series consisted of injections of 10 units of extract of the posterior lobe of the hypophysis into the left ventricle of the heart. This did not produce any accidents of the eclamptic type. Nor were any convulsive seizures elicited by injections of 5 c.c. of serum or spinal fluid from eclamptic women. No typical seizures were produced by combined intracardiac injection of extract of the posterior lobe of the hypophysis and of the serum of the normally pregnant woman. However when the guinea pig was first sensitized by intracardiac injections of distilled water followed 5 days later by 10 units of the extract, there resulted some suggestion of convulsive attacks with other symptoms of anaphylaxis and death in 3 to 5 hours. Twenty units of the post hypophyseal extract produced intense convulsions with death of the animal in a half hour. The same effects, only more intense, were produced by sensitizing the animal with the serum of the normal pregnant woman and injecting the extract of the posterior lobe of the hypophysis after 7 days. The severity of the attacks was proportional to the quantity of serum used. When the serum used was that of an eclamptic woman or a hypertensive pregnant woman the manifestations were much stormier with death in 3 minutes. Thus, an anaphylactic reaction might explain the reactions were it not for the gradations in severity with the different sensitizing media.

The author believes that the posterior lobe of the hypophysis is not of itself able to produce the eclamptic state, that a sensitization of the organism is required, that this sensitization comes from the foreign protein effects of the fetus, and that the upset comes by way of the neurovegetative, particularly the vagosympathetic, system. Thus, the calcium-magnesium salts as the regulator of the neurovegetative system are able to bring about dramatic relief.

JOHN W. BREWER, M.D.

Whitacre F E., Loeb W M Jr and Chin H:
Eclampsia *J Am M Ass.* 1947 133 445

The authors define this disease of pregnancy as probably related to nutritional deficiencies and characterized by a syndrome of symptoms and distinct pathologic lesions which are associated with angiospasm.

The present report comprises data on 100 consecutive eclamptic patients from the obstetric and gynecologic service of the Peiping Union Medical College Hospital, Peiping, China, observed during the years from 1935 to 1947. These cases are compared with those of 100 consecutive eclamptic patients from the department of obstetrics and gynecology of the University of Tennessee at Memphis observed during the years from 1941 to 1945. All the patients from Peiping were Chinese while in the Memphis series 96 were negro and 4 were white. The assertion by numerous authors that eclampsia is a disease of primiparas is borne out by the authors' cases. In the Chinese series 75 were primiparas and 25 multiparas while in the Memphis group 72 were primiparas and 28 multiparas.

With regard to the appearance of convulsions in relation to the labor in 75 of group 1 the convulsions were antepartum, in 10 intrapartum, and in 15 postpartum, while in 77 of group 2 they were antepartum in 6 intrapartum and in 17 postpartum. The stage of gestation conformed to the reports of others as in 93 patients in group 1 and 90 patients in group 2 eclampsia occurred after the sixth month of pregnancy. In both groups the disease occurred among the underprivileged or indigent who could be expected to have nutritional deficiencies.

It has been noted that the duration of hypertension might be more important than the severity of the disease that is the patient with an elevation of blood pressure which had been existent for several weeks might suffer permanent renal damage even though convulsions did not occur. However in a rapidly developing toxemia which lasted only a few days even though attended with convulsions there might be no permanent damage to the kidneys.

A study of the data contained in this report brought out several factors. Race did not seem to be significant. There was no appreciable difference in the two groups with regard to the ages and parity of the patients concerned. The stage of gestation was almost identical. The blood chemical findings are very similar and the lower blood pressures in group 1 are in accord with the low blood pressures which are found in general among the Chinese. The high incidence of eclampsia among the Chinese is significant, and the incidence in the Midsouth is unusually high. This high incidence will be reduced only when the public is better informed on the benefits of prenatal care which includes advice in regard to a properly balanced diet during pregnancy. The mortality rate among eclamptic patients in either Peiping, China or Memphis, Tennessee does not compare favorably with the mortality reported by others.

Figures on the red blood cell counts and hemoglobin determinations are somewhat lower than those commonly reported. In the toxemic group they are difficult to evaluate because of the blood dilution of pregnancy and the blood concentration associated with the toxemias. Total plasma protein determinations were not significant except when appreciably lowered.

Electroencephalographic tracings were made on 6 eclamptic patients during convulsions. All the tracings are similar but those used in this report were more clear-cut. It is significant that an eclamptic patient treated with veratrum viride gave the same type of tracing. One might contend that the alteration in the tracings is the result of the fall in blood pressure and this is probably correct for the fall in blood pressure is due to the relief of angiospasm whether by the use of regional nerve blocking or by the action of a drug such as veratrum viride.

It seems reasonable to conclude that angiospasm is probably both the immediate basis for the syndrome of eclampsia, accounting for the gradual or sudden rises in the blood pressure and the suppression of urinary excretion and the exciting cause of the convulsive seizures in some patients. The placenta is probably the stimulating factor in the patient a production of precursor substances. Methods of medical management rely for their success on the relaxation of angiospasm directly or indirectly.

CHARLES BARON, M.D.

LABOR AND ITS COMPLICATIONS

Brouse L. T.: Hemorrhage following Gestation (Hemorrhage consecutive to a gestosis) *Obst. gyn. Int. Soc.* 1946 4 749

Brouse believes that during labor uterine inertia in the eclamptic is brought about by toxic cellular edema, the excessive interstitial fluid so disorganizing the muscle fibers that atony results. In fact it is intimated that the occurrence of uterine atony angers a previous eclampsia. Moreover in such uteri intractable hemorrhage is so certain in the majority of instances that oxytocics, massage, transfusion, and stimulants may be ineffectual and, unless hysterectomy is done acute anemia or even death may ensue. The mortality figures for this condition in the author's hospital were 11 per cent and the frequency of the disorder is considerably more than is generally believed.

A subperitoneal vascular apoplexy may extend with thrombosis into the adnexa, or rupture may occur into the peritoneal cavity. Partial or total placental separation is usually associated with this apoplectic form. There does not seem to be much relationship however between the organic lesion, uterine function and the general condition of the patient. Moreover the symptoms may not follow the characteristic pattern even when there is complete detachment of the placenta nor does this accident necessarily produce fetal death in the uterus. It is said that because of the frequency of trauma

shock and the other physiologic changes caused by hemorrhage may occur readily in obstetrics. The treatment of 120 cases reported from 1936 to 1944 is discussed.

STEPHEN A. ZIEGLER M.D.

Eastman, N. J.: Pituitary Extract in Uterine Inertia. Is It Justifiable? *Am. J. Obst.* 1947 53 432.

While procedures employed in the management of uterine inertia are rather well standardized, cases of primary uterine inertia may occasionally prove refractory to treatment. The author discusses the desirability of using a really effectual uterine stimulant such as pituitary extract.

Two hundred and thirty-three ward cases at Johns Hopkins Hospital, Baltimore are considered, practically all of which were examples of true, often severe, inertia. It is emphasized that uterine inertia and prolonged labor are not synonymous, because prolonged labor may be entirely normal and physiologic, provided that steady if slow progress is made. Uterine inertia is present when there is prolonged absence of progress in the presence of weak contractions. As a rule, pituitrin was not given until from 18 to 24 hours of labor had elapsed with weak pains and a stationary cervix, and after all the usual expedients had proved ineffectual. The problem regarding pituitrin was not so much one of using pituitrin versus further temporizing as it was one of using pituitrin versus some radical method of delivery.

It is acknowledged that even if all precautions are exercised, pituitary extract, when given in the first or second stages of labor, will occasionally cause the death of the infant and, less frequently may result in rupture of the uterus; hence it is a dangerous drug when given before the birth of the baby. But, since uterine inertia also takes its toll in terms of intrapartum infection, exhaustion, difficult forceps delivery and Dührssen's incisions, the author slightly favors the use of pituitary extract, provided that these rigid rules be observed.

1 The case must be one of true uterine inertia, primary in character with labor practically at a standstill and progress nil.

2 The patient must be truly in labor, not in false or prodromal labor.

3 There must be no mechanical obstruction to easy delivery as attested by every type of evidence including x-ray study of the pelvis and fetal skull.

4 Patients of great parity having borne 4 or more children, must not be given pituitary extract because their uteri rupture more readily than those of women in the lower parity brackets.

5 The condition of the fetus must be good, as evidenced by a regular heart beat and absence of meconium stained liquor amnii. A dead fetus is no contraindication to pituitary extract.

6 The obstetrician must observe and time the first contraction after administration of the drug and give inhalations of ether if it lasts longer than 3 minutes.

7 The initial dose must not exceed $\frac{1}{4}$ minim. This dosage should not be exceeded unless it is clear

that no improvement in pains whatsoever comes. In the latter event it may be increased to 1 minim, but under no circumstances should more than 1 minim be given at a time. A period of 30 minutes must intervene between injections.

8 When there is doubt as to whether a given case meets these criteria, pituitary extract should not be given.

JOHN R. WOLFE M.D.

PUERPERIUM AND ITS COMPLICATIONS

Beecham, C. T.: An Analysis of Deaths from Postpartum Hemorrhage. *Am. J. Obst.* 1947 53 442.

The author, from the Maternal Welfare Committee of the Philadelphia County Medical Society reviews 550,489 deliveries of live and dead infants in Philadelphia during the 15 years preceding 1945, among which there were 1,987 maternal deaths. One set of mortality figures was constant over these 15 years: those due to postpartum hemorrhage, and averaged 11.4 deaths a year. The Committee has judged 78 per cent of these deaths to be preventable; 63.5 per cent were judged preventable because of errors in judgment or technique on the part of the attending obstetrician and the remainder because of factors pertaining to the patients themselves.

Two-thirds of the patients had various obstetric operations, the vast majority of which the Committee believed were not indicated. Manual dilatation of the cervix and version was uniformly condemned, as there was a very high incidence of stillbirths among the cases so treated.

Study of these 168 case reports of postpartum hemorrhage revealed that many factors had been overlooked and too often hemorrhage was the result of gross carelessness. One of the glaring omissions was good prenatal care, particularly in regard to the nutritional state and study of the blood picture. A third factor in the prophylaxis of hemorrhage is routine typing of all prenatal patients. Prophylaxis against hemorrhage is carried further in labor. The Committee records were incomplete on the indication used or its judicious application. There was even less evidence of measures employed to combat fatigue and exhaustion. Conclusions regarding anesthesia as a factor contributing toward postpartum hemorrhage were not drawn inasmuch as figures on regional anesthesia were too limited. The author lists several obvious errors in the management of the third stage of labor found by the Committee. As to the etiology of postpartum bleeding, 75 instances of bleeding from an atonic uterus were noted. The cause of the atony in most cases added up to multiple factors ranging from inadequate prenatal care to the choice of anesthetic.

Treatment in the majority of cases was far from ideal. First, there was the failure to utilize oxygen. Second, uterovaginal packing was used in only 16.5 per cent of the cases. Third, transfusions are given to only 25 per cent of the patients at a time when it could help. The amounts of blood used were inadequate, since the average was only 500 c.c. The Com-

mittee believes that these measures more than any thing else are important in combating hemorrhage. It is understood that oxytocics the Trendelenburg position and stimulation are in order but cannot compare with these three major forms of treatment.

JOHN R. WOLFF M D

Mollnengo, L.: *Carcinoma of the Rectum and the Puerperal State* (*Carcinoma del retto e stato puerperale*) *Ginecologia*, Tor 1947 13 17

The first case of carcinoma of the rectum during pregnancy was reported in 1843. During the intervening 100 years, only 55 cases have appeared in the literature.

After giving a brief resume of the cases which have been reported during the past 20 years, with the observations made by the various reporters the author reports a case of carcinoma of the rectum during pregnancy which was treated by him at the Mauriziano Hospital in Turin.

The patient was a 39 year old housewife who had had 3 normal pregnancies and a fourth pregnancy which was interrupted spontaneously one year before her first entry into the hospital on February 3, 1945. At that time she had experienced pain in the anal and perineal regions for 6 months. For 3 months the pain had increased to such an extent that it was almost unbearable. It was accompanied by constipation, painful defecation when the bowels did move and a mucosanguineous rectal discharge. She had missed 1 menstrual period.

Physical examination showed the patient to be in fairly good general condition. Pelvic examination revealed an enlargement of the uterus to the size of a 3 months pregnancy. There was a hard tumor slightly painful on palpation ill defined and occupying the median part of the posterior vaginal wall. The overlying mucosa was normal in appearance. Rectal examination revealed the presence of a tumor on the anterior rectal wall from 4 to 5 cm. in length and about 3 to 4 cm. from the anal orifice. The upper extremity of the tumor was well defined laterally it extended into the walls of the rectum. The overlying rectal mucosa was fixed to the deeper tissues and in consistency it was hard and rough because of the presence of multiple small irregularities about the size of a small pea. There was a rosy tinted rectal discharge.

The patient entered the hospital on February 3, 1945 with a tentative diagnosis of adenocarcinoma of the rectovaginal septum and pregnancy of 3 months duration. This diagnosis was confirmed after admission. Although operation was advised the patient refused surgical treatment and was discharged a week later.

A month later the patient returned to the hospital for the pain had become continuous and was relieved only by morphine. In addition the patient had experienced nausea vomiting anorexia obstipation and frequent defecations of bloody rectal discharge. Physical examination revealed pregnancy in the third month and an increase in size of the

rectal tumor which had extended in all directions. Its surface presented an irregular ulceration from 4 to 5 cm. in diameter. There was a fetid sero-sanguineous rectal discharge.

On March 12, 1945 the cervix was dilated and the uterus emptied.

On March 28, 1945 the rectum was excised by the sacroperineal route. A triangular area of the posterior vaginal wall was also excised. The vagina and perineum was reconstructed. The amputated end of the intestine was freed and brought down to the sacrococcygeal region where it was fixed.

Microscopic examination of the tumor confirmed the diagnosis of adenocarcinoma of the rectum.

Postoperative convalescence was uneventful and the patient was allowed up on the sixteenth day.

Follow up examination, a year later, revealed the patient to be in good condition both subjectively and objectively. The vagina had cicatrized perfectly and allowed conjugal relations. The sacral anus was functioning satisfactorily.

On account of the rarity of the finding of carcinoma of the rectum during pregnancy there have been numerous speculations as to the reason for it. The 2 most common explanations are (1) that carcinoma of the rectum is rarer in females than in males, and (2) that it appears most often in the fifth decade of life when fecundity in the female has practically disappeared.

Of the 55 patients with carcinoma of the rectum during pregnancy whose cases were reported the youngest was a woman of 18 years while the oldest was a woman of 43 years. According to age the 55 patients were found to be as follows: 1 was less than 20 years of age, 7 were between 21 and 25 years, 12 between 26 and 30 years, 11 between 31 and 35 years, 10 between 36 and 40 years, and 5 between 41 and 45 years.

Carcinoma of the rectum in general occurs most frequently in the fifth decade of life but carcinoma of the rectum during pregnancy occurs most often before or during the third decade of life.

Pregnancy may be a predisposing factor in the production of carcinoma of the rectum. During pregnancy there is an increased congestion in all of the pelvic organs. Pressure is exerted on the rectum and hemorrhoids occur as a common complication of the pregnant state. Hemorrhoids ulcerate and give rise to bloody discharges. This may lead to more serious changes.

Pregnancy may in some way be the cause of producing cancer of the rectum and cancer in general. Two cases are cited by the author from the literature in which several cancers occurred during pregnancies in the same woman. One woman of 31 years was operated upon for cancer of the rectum following delivery she was well for 7 years when another pregnancy was interrupted spontaneously at the fifth month. Two months later she developed intestinal obstruction due to a cancer of the ascending colon. Four years later at the menopause she was treated for cancer of the bladder.

Another patient, a multipara 32 years of age, with a hereditary neoplastic history was operated upon for carcinoma of the rectosigmoid flexure after her eighth delivery. She was well for 8 years then 20 days after a normal delivery of her ninth child she underwent an operation for cancer of the rectum, which had invaginated into the ascending colon. Two years later the patient delivered her tenth child prematurely at the eighth month at which time a stenosing cancer of the artificial anus (made during her second operation) adhering to the posterior vaginal wall, was removed. In these last 2 cases, the pregnancy seemed to have some direct connection with the appearance of the tumors. To avoid recurrence of malignancy during pregnancies, sterilization has been recommended as a prophylactic measure.

Carcinoma of the rectum during pregnancy may be easily overlooked. Whenever untoward signs or symptoms develop rectal examination should be made for such common signs as bleeding hemorrhoids, discomfort from intrapelvic pressure and constipation as they may be due to the presence of a cancer of the rectum.

If cancer of the rectum is diagnosed as inoperable late in pregnancy delivery by cesarean section when the child is viable, is recommended to save the life of the child. Palliative x ray treatment may then be given to the mother.

If inoperable cancer is discovered early in pregnancy it is deemed advisable to induce abortion and then administer vigorous therapy by means of roentgen irradiation.

When cancer is deemed operable radical removal of the cancer of the rectum should be done immediately to benefit the mother irrespective of the life of the child. Abortion may or may not be done before the radical operation. If the patient undergoes radical operation and the pregnancy goes on to term, then delivery by cesarean section is regarded as being the safest method.

BLACKWELL MARKHAM, M.D.

MISCELLANEOUS

Romero, C. G.: Alterations of Body Weight during Gestation, Parturition, and the Puerperium (Las alteraciones del peso corporal durante la gestación, parto y puerperio) *Rev. esp. obst. ginec.* 1945, 3: 15

Alterations in the body weight of the pregnant woman were closely studied during a 2 year period at the author's clinic. It was possible to classify the patients into four groups.

1. The normal group in which increase in weight was constant and gradual ranging between 500 and 1,500 gm., with a sudden transient rise during the seventh month.

2. This group is characterized by a rapid rise during the first 3 months probably due to endocrine hyperfunction. Adjustment occurs and the weight curve follows according to the normal range during the latter months of pregnancy.

3. This group has an increase in weight along normal lines up to the seventh month. Then there is a sudden exaggerated increase for metabolic reasons with the formation of edema. These changes are considered pathologic.

4. The fourth group may have a diminution or no appreciable weight change during the first 3 months. Then there is an irregular weight increase inasmuch as the gain is under the normal. The cause is considered to be of neurovegetative origin, such as a lack of appetite vomiting or hyperemesis, during the early months of pregnancy.

The multiparas show a slightly greater increase in weight than the primiparas. Constitution and stature have some influence as well as twin pregnancy and such chronic processes as heart disease tuberculosis diabetes asthma nephritis, and lung.

Among the causes enumerated for weight increase are amniotic fluid size of the uterus and placenta, endocrine imbalance salt retention, capillary permeability hypoproteinemia nephritic and pre-eclamptic edema, and deranged water metabolism.

STEPHEN A. ZIEGLER, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Piero, C.: Suprarenal Apoplexy Associated with Sepsis (Apoplexia surrenalis in decurso di sepsi) *Minerva med.* Tor 1947 38 146.

A 40 year old woman entered the hospital with mild symptoms referable to the right lower quadrant and died on the sixth day of her hospital course. Autopsy findings included evidence of bronchopneumonia, with generalized sepsis and hemorrhagic phenomena involving the brain and meninges as well as the serous membranes of the abdomen and thorax the right ovary the left kidney and the suprarenal glands.

The author points out that the course did not conform strictly to descriptions of the Waterhouse-Friderichsen syndrome but that the finding of gross hemorrhage in the suprarenal glands justified consideration of that classification.

He postulates that the illness began with an episode of bronchopneumonia which developed into generalized sepsis and that the response to the generalized invasion was essentially a sensitized one manifested by hemorrhages and exudative changes involving the myocardium spleen kidneys, leptomeninges, liver and suprarenal glands. The organism isolated was the *Pneumococcus* rather than the meningococcus described in connection with the Waterhouse-Friderichsen syndrome. However the pathogenesis conformed so well to that of this syndrome that the hypothesis that bacteria other than the meningococcus could produce this clinical entity seemed justified, provided that opportunity had been given for the sensitization of the skin and suprarenal glands. EDITH B. FARNSWORTH M.D.

Bacon, S. K.: Hydronephrosis of Supernumerary Kidney *J Urol* Balt. 1947 57 459

Supernumerary kidney is a rare anomaly which occurs when duplicated or bifurcated excretory ducts extend cranially to enter two independent metanephrogenic masses. They develop into two separate renal entities. The following case of hydronephrosis of a supernumerary kidney is presented.

A woman, age 47, was admitted to the hospital for right lower quadrant pain of many years duration, and right lower quadrant tenderness without masses. Appendectomy was done after the finding of a mass of intraperitoneal adhesions. One particularly prominent band was encountered, which might possibly have been a right ureter. One week after operation the right side of the abdomen began to enlarge. On the thirty first day, examination revealed the presence of a large cystic mass in the entire right side of the abdomen. Cystoscopic studies revealed an enormous right hydronephrosis with normal appearing renal substance above it. With indwelling catheter drainage the mass disap-

peared. It was concluded from x ray studies that a normally formed right kidney existed above the hydronephrosis. At operation two separate kidneys were found. The cranial organ was normal. The caudal kidney presented a far advanced hydronephrosis which was densely adherent to the peritoneum, colon, and vena cava. The organ was removed and the postoperative course was uneventful save that a ureteral stricture was discovered which responded to dilatation. ROBERT O. BEADLES, M.D.

Engel, W. J.: Calicectomy for Stone *J Urol* Balt. 1947 57 619

The good result obtained by partial nephrectomy in a group of 9 patients with caliectasis from stone 5 years or more after operation prompts the author to report this series. The operation is indicated in patients with dilated upper or lower calyces containing calculi in whom it seems apparent that simple removal of the stones would leave behind an abnormal calyx in which urinary stasis would favor the formation of stone. In all of these cases the operation was deliberately planned following urologic study, a method preferable to decision at the operating table.

The technique is described as employing the usual oblique lumbar incision spinal anesthesia generally being used. A cobbler type stitch across the pole to be resected controls the bleeding. This stitch is placed as soon as the pole is mobilized and before the capsule is incised (Fig. 1). After it is snugly tied,

Fig. 1 (Engel) Diagrammatic sketch showing placement of cobbler type of stitch for renal compression. A, First stitch has been placed. B, Second is being started by inserting needles from opposite surfaces of kidney. Catgut suture, with double end straight, atraumatic needles, is employed. C, Shows suture completed and tied on opposite side of kidney.

Fig. 2. (Engel). Showing various steps in operation for partial nephrectomy

an elliptical incision is made in the capsule distal to the line of suture, and the capsule is stripped back. The pole is then removed by a wedge shaped incision and the capsule is sutured across the cut surface with interrupted mattress sutures (Fig. 2). If there is some bleeding a piece of muscle or fat is sutured against the cut surface, or a thrombin impregnated absorbable sponge may be used. Nephrostomy or pyelostomy drainage was not employed and there were no postoperative fistulas. In all cases drainage was placed to the operative site.

A review of the series reveals no operative deaths. The average postoperative stay was 13 days, with a minimum of 11 days and a maximum of 15 days. Observation of these patients for from 5 to 13 years following operation reveals no case of recurrent stone. In all of the patients the remaining portion of the kidney is functionally active as measured by diatriz excretion in the intravenous urogram and in several patients the kidney pelvis appears almost normal. In 8 of the 9 cases there was evidence of urinary infection at the time of operation however in all cases the urine was negative at the time of the most recent follow-up examination. Sufficient functioning renal tissue is conserved to sustain life should disease or injury destroy the opposite kidney.

JOSEPH E. MATTHEW, M.D.

FRANZES, F: Pararenal Abscesses. *Acta. chir. scand.*, 1946 94 Supp. 116

FRANZES studied 100 cases of pararenal (perinephritic) abscesses 85 of which were followed up for

periods ranging from 2 months to 16 years after discharge from the hospital. Operation was performed on 97 patients. Pararenal suppuration occurred on the right side in two-thirds of the cases, and it affected the rural population 6 1/4 times as often as the urban population.

Contaneous foci of infection, such as furunculosis, cellulitis, and wounds, caused pararenal infection most often. In 10 per cent of the cases trauma to the lumbar region was the primary cause. Physical exertion was also of etiologic importance. Chronic renal disease was of etiologic significance in about 5 per cent of the cases. Abdominal, thoracic, and genital inflammatory processes caused pararenal infection in relatively few cases.

Urinary abnormalities are not of diagnostic importance. On the other hand, the roentgenogram is of importance. In 16 of 17 cases examined, mobility of the diaphragm was reduced on the affected side. In 21 of 24 instances the delineation of the psoas muscle was absent. In 14 of 21 cases pleuritis was discernible, and in 11 instances an exudate in the pleural cavity was found. Diagnostically the roentgenologic findings were more important than the pyelogram which elicited hydronephrosis (caused by ureteral compression) in a few cases.

The diagnostic puncture is of value and should be performed in several directions if pus is not obtained on the initial examination. The danger of intercostal perforation is slight.

Treatment by incision alone is insufficient. The abscess cavity should be explored and multifocal retention pockets broken up to promote perfect drainage and to avoid retention of collections of pus. Nonfatal complications occurred in 9 cases. The mortality rate in this series of cases was 19 per cent.

ROBERT TUNELL, M.D.

KILIK, M: Extraction of Ureteral Stones. *J. Cui Balt.*, 947 57 473.

The instrument. The Balkus modification of the Zeiss looped catheter was used by the author because the materials needed were readily at hand. It was found that 5 F whistle tipped catheters and No. 31 to 35 steel suture wire were the most adaptable. With some personal modifications this apparatus was used throughout the study. These modifications were as follows: (1) the length of the loop was varied between 5 and 7 cm., with an optimum of 6.5 cm. (2) more lightly radiopaque than the standard x-ray catheters were employed for better contrast with stone shadows (3) a marker was placed 2 cm. distal to the tip of the closed loop to signal its approach to the bladder (4) another marker was included on the pull filament to denote closure of the loop (5) progressive changes in the type and installation of filaments were made because troublesome kinks sometimes occurred in the steel suture wire (the most satisfactory material proved to be dermalon, size 0 or 00) (6) it is planned to flatten and stiffen the loop to improve stone fixation and to insure a wide open noose.

The technique for the successful use of this instrument includes certain refinements. For purposes of organization, it may be divided into 5 parts: (1) preparation of the patient (2) passage of instrument (3) formation of loop (4) engagement of stone (5) mode of traction.

1. Preparation of the patient. Preliminary cystoscopy and retrograde pyelography are the rule. These procedures are considered manipulative whether the diagnostic catheter passes by the stone or not. Thereafter spontaneous passage is awaited for 3 to 5 days before extraction is attempted.

2. Passage of instrument. Any cystoscope permitting the passage of 5 F catheters suffices. Rubber tip connectors with large loose eyes are important. Cold water for irrigation insures maximum catheter rigidity. The loop must be tested before insertion, and lubrication of the filament within the lumen of the catheter is wise. The most important factor in the passage of the instrument by the stone is patience. After passing by the stone, the catheter is left indwelling for 10 minutes. Before its removal the renal pelvis is filled with air. The impression has been gained that air in the ureter being moved by peristalsis loosens and shifts the stone. The instrument is then passed by the calculus through the channel recently vacated by the indwelling catheter.

3. Formation of the loop. The instrument is always passed to the pelvis if possible. Although the loop can be formed in the ureter this maneuver is much easier in the wide pelvic area. One hand pushes on the catheter as the other pulls on the filament. A marker on the pull filament measures the change but in addition a slight tap is felt as the tip of the catheter hits its sides upon completion of closure.

4. Engagement of the stone. The loop is trolled down the ureter under cystoscopic vision of the ureteral orifice. All pull is confined to the filament to maintain complete closure of the loop. Pull is continued through the cystoscope until the stone is engaged or the tip of the loop appears in the bladder, after which the cystoscope is removed. The tip of the loop eventually catches on the sheath and prevents further traction. Extreme patience and deliberation are essential in drawing the loop down the ureter. Ten seconds per centimeter have been found quite satisfactory before the stone is engaged, and affords sufficient time for the stone to drop into the noose. Engagement produces a certain hang or tug, whereas passage of the loop down a normal ureter is unimpeded. The tip of the loop may hang on the ureteral orifice but a slight twist usually releases it. Roentgen rays are used to confirm engagement.

5. Mode of traction. All traction in this study has been manual. Continuous pull has never been used and contraptions applicable to such have not been employed. Manual traction has been restricted to doctors whether the patient has been on the cystoscopic table or in bed. If the stone resists a 2 pound pull over a reasonable period of time, the ap-

paratus is left indwelling. Many have been left indwelling from a few hours to 6 days. A maximum pull of 3 pounds is exerted 3 or 4 times daily if necessary. Traction is confined to the filament unless a knot has fixed this to the catheter. Between pulls the end of the apparatus is taped to the patient's abdomen. Traction is steady or intermittently deliberate never jerky. A small spring type scale may be used to determine the weight of pull, when desired. If the stone becomes disengaged it is either relooped immediately or later as the case might be.

The results obtained were as follows:

Every stone which could be passed by and engaged was extracted, except one. A small stone in the intramural segment which could not be passed by again after disengagement. Transvesical ureterolithotomy proved necessary because of obstruction and infection. This failure may rightfully be blamed on the operator's inexperience, and impatience at the time of traction. Certainly it was not the fault of the instrument. Sixteen stones could not be passed by with any instrument at any time and 10 of these were removed by operation. The remaining 6 stones were smaller and passed spontaneously after manipulation.

JOHN A. LOXRY, M.D.

Young, J. N.: Retrocaval Ureter with Description of an Operative Case Complicated by Ureteric Calculus. *Brit J Urol* 1947 19 55

The thirty-sixth case of retrocaval ureter is reported and the embryology and literature of this rare anomaly are briefly discussed. Of the 35 cases previously described 12 were found at operation and 23 at autopsy. There are no symptoms typical of this condition.

The case reported was that of a 24 year old female dwarf who was hospitalized for right renal colic. X-ray examination demonstrated a calculus lying to the right of the lumbar vertebra and small calculi in the left kidney. Intravenous urography showed a right hydronephrosis and the ipsilateral renal pelvis was poorly visualized.

At operation the ureter was found to pass medially behind the vena cava about 2 inches from the ureteropelvic junction. The calculus was found in the ureter as it emerged from behind the vena cava. The calculus was removed.

A plastic procedure was not done to remove the ureter from behind the vena cava since the dilatation of the right kidney was thought to be adequately explained by the presence of the ureteral calculus. The postoperative course was uneventful.

ROBERT LICH, JR., M.D.

Davalos, A.: A New Technique of Ureterointestinal Anastomosis. *J Urol* Balt., 1947 59 701

The technique which is to be described was carried out on 17 dogs, with excellent results in 8 of the 15 dogs thus far sacrificed. Fair results in 4, and a poor result in 1 dog. In 2 instances the results were not known. The purpose of this work was to attempt to develop a procedure that would be applicable to

Fig. (D yakov) 1. Preparing longitudinal trough. 2. Anchoring left ureter to submucosa. 3. Closing longitudinal trough with fine silk. 4. Mattress suture of fine silk placed in edges of incision. Making ostium in sigmoid. 5. Placing anchoring suture in mucosal flap. 6. Tying mattress suture as tension is made on anchoring suture.

early cases of carcinoma of the bladder which would be free of many of the hazards of previously described methods, and which would permit visualization of the uncompressed ureter emptying into the bowel.

The preoperative preparation took 3 days. During the first day a clear fluid diet was given, along with sulfadiazine and an enema was given that night. On the second day, the preparation was the same except that magnesium sulfate was given in addition and on the third day water alone was permitted by mouth the chemotherapy was continued, and the patient was given an infusion of 2,000 c.c. of

10 per cent glucose in saline solution, hard candy and 1 c.c. of prostigmin (1:2,000) every 6 hours. Enemas were given at night until the return was clear and on the day of operation the parenteral fluids, sulfonamides, and prostigmin were continued.

Continuous spinal anesthesia was used, and the ureters were approached transperitoneally through a transverse suprapubic incision which divided the recti. After the ureters were severed from the bladder a point on the anterior aspect of the rectosigmoid was chosen which was free of mesenteric circulation. A 3½ cm. transverse incision was made in the sigmoid to expose the submucosa. A small incision

sion was made in the upper border of the wound to form a trough as shown in the illustration and after the ureter was placed in this trough it was closed with two interrupted fine silk sutures. Mattress sutures of fine silk were then placed in the wound to draw the edges of the transverse incision over the ureter. The mucosa was then incised transversely and an anchoring fine catgut suture was placed in the mucosa to draw the ureter into the bowel. The mattress sutures were then tied and a single additional interrupted suture was placed between the mattress sutures to reinforce the closure. The transplant area was then covered with the posterior reflexion of peritoneum to extraperitonealize the operative area and fix the sigmoid and thus prevent tension. The same procedure was followed in transplanting the opposite ureter. The right ureter was usually transplanted first. The author also illustrates this technique in transplanting a double ureter.

Inserting a small silver cannula in the intramural ureter. The cannula, attached to the outside by a black silk suture, is removed in 96 hours. In determining the amount of heat that can be safely applied without destruction of the bladder wall, the tolerance of the gloved finger held in the vagina or rectum is used as a criterion.

Deep x ray treatment is recommended as a therapeutic adjunct in the treatment of bladder tumors.

CLARENCE V. HODGES, M.D.

Ritter, J. S.: Cystectomy for Carcinoma of the Bladder. *J Urol* Balt. 1947 57 719.

The author states that once the diagnosis of infiltrating cancer of the bladder has been made, total cystectomy is the procedure of choice. He favors bilateral cutaneous ureterostomy rather than ureteroenteric anastomosis for diversion of the urinary stream.

In 7 cases the perineoabdominal technique of total cystectomy with implantation of the ureters to the skin, was carried out. The entire procedure was performed at one sitting in from 1 to 1 1/2 hours. There were no operative deaths.

With the patient in the exaggerated lithotomy position the usual perineal exposure is made as for perineal prostatectomy. The membranous urethra is divided and ligated. The prostate, seminal vesicles and bladder neck are then mobilized posteriorly laterally and anteriorly as high up as one can reach. After wrapping a large lap pad around the free end of the urethra, the mobilized portions are thrust up into the pelvis. The perineal wound is closed around a small Penrose drain. With the patient in the dorsal position a transverse suprapubic incision is made about 4 cm above the symphysis pubis, through the skin and anterior rectus sheath. The recti muscles being separated vertically the transversalis fascia is separated from the under surface of the symphysis pubis. After separating the bladder and peritoneum laterally down to the origin of the obliterated hypogastric arteries, the separated prostatic extremity is brought upward, and the bladder prostate, and seminal vesicles are separated posteriorly from the rectum. The mobilization of the bladder is carried out in a retrograde manner. As the ureters are encountered, they are clamped, cut close to the bladder and intubated. The vessels supplying the bladder are clamped, divided and ligated as they are encountered. The intimate peritoneal attachment overlying the bladder is clamped, the bladder is cut away and the peritoneum sutured. The wound is packed with iodoform gauze, the packing being brought out through the wound. The ureter on either side is freed retroperitoneally and brought out to the skin surface through a stab wound preferably in the posterior axillary line.

The author also suggests that the total cystectomy procedure here described be employed in cases of carcinoma of the prostate gland.

CLARENCE V. HODGES, M.D.

BLADDER, URETHRA, AND PENIS

Corbun, B. C. and Corbun, B. C. Jr.: Thermal Treatment of Vesical Tumors. *J Urol* Balt., 1947 57 739.

The authors present a plea for the more universal application of electrically induced heat in the treatment of bladder cancer. They believe that tissue coagulation, because of additional penetration is far superior to fulguration.

Tumors from 1 to 1 1/2 cm. in diameter are handled adequately by transurethral methods. When transurethral electrocoagulation with bipolar current is employed, it is necessary to use the largest active electrode passable through an operating cystoscope. If there is any recurrence a suprapubic cystotomy and electrocoagulation of the tumor followed by x ray therapy should be performed.

All large tumors should be treated transvesically. Use of the flat metal disc as the active electrode produces the maximum amount of available heat in destroying a tumor involving or adjacent to, the prostatic urethrum. damage to the ostium is avoided by

Tashiro, S., and Hinman, F., Jr.: Perirethral and Perirectal Infections. *J Urol Balt* 947 57 338.

Attempts to interpret the clinical distribution of perirethral phlegmon along the classical fascial planes which limit sterile extravasated urine may delay diagnosis and confuse attempts at rational treatment. Many of these septs break down under the influence of infected urine and pus and allow dissemination of infection with little regard for the classical routes of spread.

Extravasation from the penile urethra may be limited to the penis by Buck's fascia, or may penetrate this layer and spread beneath Colles fascia, similar to its spread after perforation of the bulbous urethra.

Most commonly the infection begins in the bulbous and bulbomembranous urethra, since this is the most frequent site of stricture and penurethritis. Infection erodes and dissects anteriorly in the space beneath Colles fascia (since this area is proximal to the origin of Buck's fascia) and over the abdomen beneath Scarpa's fascia. In an occasional case it will spread posteriorly and break through Colles fascia beneath the superficial transverse perineal muscle and enter the ischio-rectal fossa.

If the defect occurs in the membranous urethra, the infection fills the potential space between the superior and inferior layers of the urogenital diaphragm and usually breaks out through the inferior layer to spread anteriorly beneath Colles fascia. It may ascend through the superior layer and thence into the retroprostatic tissue or into the anterior prolongations of the ischio-rectal fossa. Lastly it may break directly through the posterior fascia of the urogenital diaphragm into either ischio-rectal fossa.

Perforation of the membranous urethra at its junction with the prostatic urethra, on the pelvic side of the urogenital diaphragm, allows access of the infection to the ischio-rectal fossae by way of their anterior prolongations.

Because of the low resistance of the loose areolar tissue of the perirectal area and the weakness of the superficial pelvic fascia compared to Colles fascia, periurethral infections from any part of the posterior urethra may appear at the surface about the rectum before superficial changes are observed in the urethral area and anterior perineum.

A perirectal abscess usually arises from an infected rectal crypt or mucous gland, enlarges in the ischio-rectal or superficial perirectal space and eventually ruptures spontaneously either into the rectum or through the skin of the posterior perineum. More often than is generally thought the infection will pass beneath the superficial transverse perineal muscle and localize about the bulbous urethra. It may then spread about the genitalia and over the abdominal wall. The perirectal abscess may also fill the anterior prolongations of the ischio-rectal fossa and thereby impinge on the upper end of the membranous urethra as it emerges from the urogenital diaphragm, or it may compress or cause thrombosis of

the internal pudendal vessels as they come along the lateral wall of the ischio-rectal space. Any of these alternatives may cause urinary difficulty.

In the experience of the authors, perirethral phlegmon and far advanced perirectal abscess frequently have not been differentiated before operation. It is important to differentiate between these diseases preoperatively because the surgical treatment differs in important respects. In extravasation (septic or sterile) the necessity for immediate crico-tomy in addition to radical incision is evident, whereas spreading perirectal infections demand adequate and often extensive incision and drainage but crico-tomy may not be indicated. Furthermore extravasation is usually a urological problem while perirectal abscess is treated either by the proctologist or the general surgeon.

The history of urethral inflammation or stricture is contrasted with the history of cryptitis or hemorrhoids. Dysuria or retention are more likely to indicate periurethral disease, whereas rectal pain and constipation point to involvement of the perirectal tissues. Gross contamination of the urine means major urethral involvement, while mild pyuria may be found in cases of rectal infection with anterior extension.

FREDERICK A. LLOYD, M.D.

Lowmley O. S., and Gentile, A.: Operation for Peyronie's Disease. *J Urol Balt*, 1947 57 152

The operation for Peyronie's disease is done under spinal anesthesia. A tourniquet is placed around the base of the penis and an incision is made on the dorsal surface of the penis, deepened through the skin, subcutaneous tissue, and fascia, down to the fibrous tissue between the corpora cavernosa. The fibrous tissue and associated plaques are dissected free and removed, care being taken to leave as many venules as possible when Buck's fascia is involved in its mesial portion as it usually is. A strip of fat is then sutured in place, care being taken not to approximate the edges of Buck's fascia. This precaution is taken because it has been found that the scar resulting from the healing of one side to the other has reproduced the condition to a certain extent. Therefore, the edges are not allowed to come in contact, one with the other. The tourniquet is released, and necessary pressure is re-introduced if bleeding occurs. The subcutaneous tissue is returned snugly over the fat and the nonapproximated edges of Buck's fascia. This is done with No. 3 plain catgut. The skin is then sutured with silk.

A moderately snug bandage is placed around the penis to create sufficient pressure to ensure hemostasis.

The results are summarized as follows:

"Our experience with operations upon the penis for the cure of Peyronie's disease extends from 1911 down to the present, most of the operations having been done after 1935. Our patients have included men in all decades of life, the youngest being 27 years of age and the oldest 70 years. Our failures have resulted from attempting to operate upon men who

have had too extensive lesions that is areas of in duration extending beyond the summit of the corpus cavernosum on either or both sides.

In the early years of our experience with this disease we operated only upon those patients who had tried every form of nonoperative treatment, but now our results justify operating upon any early case.

JOHN A. LOFF, M.D.

Schrek, R. and Lenowitz, H.: Etiologic Factors in Carcinoma of the Penis. *Cancer Res.* 1947 7 180.

In the present study the authors evaluate the significance of venereal disease, circumcision, age, and race as etiological factors in carcinoma of the penis and illustrate the use of control groups.

The statistical studies with charts and explanations are well presented and should be consulted by the interested reader. They do not lend themselves to condensation. A comparison of data assembled from the clinical and control groups suggests that there are two fundamental etiological factors in carcinoma of the penis: (1) circumcision in early life seems to offer almost complete protection against penile cancer and explains the almost complete absence of the condition in Jewish men; (2) poor sex hygiene appears to be responsible for (a) the high incidence of venereal disease in men with carcinoma of the penis, (b) the relatively greater frequency of carcinoma of the penis in colored men, and (c) the high incidence of syphilis in men with a history of gonorrhea.

The authors found that in the groups with carcinoma of the penis as compared with the control groups there was a high percentage of negroes, a high incidence of syphilis and gonorrhea, a very low incidence of circumcision early in life, and the same incidence of circumcision during boyhood and early manhood. Positive correlations were obtained for the factors indicated as (1) carcinoma of the penis (2) syphilis, (3) gonorrhea, and (4) the colored race. The common denominator in these four factors seems to be poor sex hygiene. It may be concluded that the incidence of carcinoma of the penis could be reduced by early circumcision or by good sex hygiene.

ROBERT O. BEAULIEU, M.D.

GENITAL ORGANS

Dees, J. E.: Congenital Cyst of Prostate. *J. Urol.*, Balt., 1947 57 304.

Dees reports a 26 year old male who was seen because of perineal discomfort and difficult urination. He had a history of intermittent attacks of low back ache treated by prostatic massage which caused the discomfort to disappear immediately. He had been married for 5 years, but no pregnancies had occurred and several studies of the ejaculated semen failed to show spermatozoa. On examination, the right lateral lobe of the prostate was greatly enlarged, soft and compressible. It extended slightly across the midline of the prostate and down over the apex of the gland laterally to the pelvic wall and upward for a short

distance over the base of the bladder. The lateral margin of the left lateral lobe was normal to palpation. Above and to the left of the cystic mass between the rectum and the base of the bladder could be felt several cordlike structures one of which was presumed to be the left seminal vesicle. The expressed prostatic secretion contained from 20 to 30 leucocytes per high power field. The second glass of urine was microscopically negative. Excretory urograms showed a normal left ureter and kidney and no evidence of excretion of dye by a right kidney. Cystoscopy revealed great enlargement of the right lateral lobe of the prostate which displaced the prostatic urethra well across the midline and obscured the entire right half of the trigone and region of the right ureteral orifice. Subsequent cystoscopy demonstrated absence of the right half of the trigone and its ureteral orifice. The left ureteral orifice and trigone were normal.

At operation the prostate was exposed perineally and the large tense bulging right lateral lobe was incised. A cavity was entered which contained 3 ounces of dark fluid. The cavity extended upward toward the region of the right seminal vesicle. The cyst fluid was compatible with normal seminal fluid except that the count was 450 million per cubic centimeter. There was an increase in abnormal forms, and no motile spermatozoa were observed. Subsequently 300 c.c. of air were introduced into the bladder and 20 c.c. of skodan solution were introduced into the cavity through the previously inserted rubber tube. The cavity was lobulated but smooth walled, and 4 cm. in diameter and a tubular structure resembling the right ureter was filled up to the pelvic brim. No suggestion of a renal pelvis was seen. A second irregular tortuous tubular structure was filled, which later turned out to be a redundant right vas deferens. Later the right vas was exposed in the scrotum and injected with skodan. It communicated with the prostatic cyst. The authors relate as follows:

A large cystic cavity occupied the right lateral lobe of the prostate, but did not communicate with the urethra, and both the rudimentary right ureter and the right vas which was dilated and tortuous in its terminal portion, opened into this cavity. Distention and enlargement of the right epididymis were also present.

The findings are explained embryologically as a failure of communication between the wolffian duct and the vesicourethral primordium. Although the ureteral bud developed into a rudimentary ureter its lower end was not absorbed into the developing bladder and urethra, and therefore the ureteral orifice retained its early embryological location in close relationship to the lower end of the wolffian duct.

DAVID ROSENBLUTH, M.D.

Herbut, P. A. and Lubin, E. N.: Cancer Cells in Prostatic Secretions. *J. Urol.*, Balt., 1947 57 542.

To corroborate a clinical diagnosis of carcinoma of the prostate, cancer tissue must be demonstrated

INTERNATIONAL ABSTRACTS OF SURGERY

276

microscopically. Conventionally, tissue for histologic study is obtained at biopsy by way of perineal exposure by transanal resection, or by removing the entire prostate. In the early stages, however, the former two are not always fool-proof for the biopsy may not be secured from the right spot or the urethral portion of the prostate may not contain the carcinoma. In addition to these methods three other procedures of securing material for microscopic study have been advocated: (1) aspiration biopsy of a nodule suspected of being carcinoma, (2) punch biopsy from a similar area, and (3) the demonstration of cancer cells in urine. Each of these is beset with serious difficulties for both aspiration and punch biopsies preclude the precise localization of the cancer by rectal palpation, and this is open to the objections already cited, whereas the demonstration of cancer cells in urine necessitates exfoliation of neoplastic tissue into the bladder which is a late feature in this disease.

Secretions are secured by digitally massaging the prostate in the rectum, or by collecting on clean glass slides at the meatus they are collected on clean glass slides and smeared evenly and thinly by covering with another slide and are pulled apart and while still wet they are immediately fixed in equal parts of 95 per cent alcohol and ether. They should remain in the fixative for at least 15 minutes, after which they are stained by the Papancolou technique. Stained smears are examined microscopically first with 60 magnification and, if irregular cells are found, with 400 magnification in a systematic manner so that all portions of the slide are inspected. If cancer cells are numerous they may be detected in a few seconds but if they are scanty or absent it takes approximately 30 minutes to examine 6 slides adequately.

In normal hyperplasia, or early cancerous prostate the quantity of secretion varies from 1 to 3 cc. but when the organ has been converted into a stony mass the quantity diminishes to a drop or two. Normally the secretions are opalescent and pearly white or gray. They are unaltered in carcinoma except when the organ becomes hard and it becomes thin watery and of a poor quality.

Noncancerous secretions. Secretions from entirely normal prostates disclose a paucity of cellular elements. The protein precipitates out in the form of minute light green granules. Scattered here and there one finds a few large flat pol. bled or irregular pavement cells that are doubtless derived from the urethral mucosa. Their cytoplasm is abundant light green and sharply defined, and the nuclei are small, round and evenly stained. Prostatic epithelium cells are much smaller than pavement cells. They are single, sometimes in clumps of 2 or 3 polygonal or cuboidal, sharply defined, have a moderate amount of light green cytoplasm, and may not be present in modular hyperplasia. The prostatic epithelium is increased in amount. The cells are usually

a little larger but are otherwise generally the same. Cuboidal cells are sometimes arranged in rows of many as one-half dozen, and at other times polygonal cells of equal numbers may be irregularly clustered together. In each instance the cytoplasm is light green, the cells are regular, and their borders are always sharp and distinct. Sometimes, if considerable pressure is exerted in preparing the smear, the cytoplasm may be considerably drawn out, but even in such cells the same characteristics are not detected. The regularity of the cells is the best illustrated in tissue smears of normal and hyperplastic prostates. In addition to simple cells there are large sheets of polyhedral cells with sharp distinct borders, light green nuclei. In secretions from hypertrophied prostates there are often numerous large central, regular nuclei. In secretions from atrophic and round eccentric nuclei. Concentric, debris cells with reticulated or vacuolated cytoplasm and neutrophils, plasma cells, lymphocytes, and erythrocytes are also present in secretions from prostates with prostatitis. With the exception that both neutrophils and fibrin dominate the picture.

Cancerous secretions. Because carcinoma of the prostate is associated with a normal, hypertrophied or chronically inflamed prostate, the cells in the secretions vary accordingly. In addition to the usual cellular elements, however, some cancerous prostates reveal numerous large flat pavement cells that are all colors of the rainbow. As already noted, these cells are very few in number in noncancerous prostates where they generally stain in light green shades. Aside from pavement cells, all cases of carcinoma have in this series, in which the secretions are disclosed. As might be expected, the latter vary considerably from case to case, depending upon the histologic structure of the carcinoma. But the striking feature is nevertheless, constant enough to enable one to anticipate the type of cancer. In well differentiated adenocarcinoma, smears of secretions usually disclose large or small, solid sheets of cancer cells, close large or rounded, well defined or sharply irregular flat or rounded, well defined or sharply delineated margins. The cell boundaries are almost indistinct or entirely unperceptible. It is scanty fibrin plasma tends to become confluent. It is scanty fibrin, grayish green, oval or round, deeply and evenly stained, and may or may not contain nuclei. The nuclei are relatively large, oval or round, deeply and evenly stained throughout the smears are a few scattered similar single cells with moderate or scanty cytoplasm. In ill-defined and peripherally frayed, cytoplasm. In carcinomas in which irregular cells are not as well defined with large somewhat irregular cells that are not as well defined clusters of cancer cells in the former group. The cells are as dense as the cells in the former group. The cells are spread thinner and are often drawn out into long pointed projections. The cells vary in size but as a rule they are larger than those in the more differentiated tumors. The cytoplasm is abundant although relatively decreased, stainlightly and

is of a blue green or yellowish green color. The nuclei are large, round sharply defined and are rimmed with a distinct membrane. They disclose watery almost vacuolated, lightly stained nucleoplasm and a sharply circumscribed deep blue to black, centrally placed nucleolus. Single tumor cells scattered throughout the smears are essentially similar. Cancer cells in secretions from completely undifferentiated carcinomas likewise vary somewhat from patient to patient. Characteristically however they are found singly if in clusters they are only loosely adherent to each other. The cells are comparatively small, have a moderate or scanty amount of ill-defined, peripherally frayed, yellowish gray or green cytoplasm and relatively large, round or oval, evenly but deeply stained nuclei. In cancers composed of large round, oval or polygonal cells with reticulated or vacuolated cytoplasm, the secretions usually reveal clusters of cells with scalloped margins. The cell boundaries, in contrast to those from other types of carcinoma, are quite distinct. The cytoplasm is reticulated or actually vacuolated, and the nuclei are round or oval and centrally or eccentrically placed. Apart from the aforementioned clear cut types carcinoma of the prostate frequently shows combinations of the various patterns which are reflected almost as clearly in smears of the secretions as they are in histologic sections.

In conclusion, the authors state that a cytologic diagnosis of carcinoma of the prostate from smears was rendered 17 times. The diagnosis was confirmed histologically in 10 cases and was reasonably certain clinically in an additional 6 cases. Some of the patients will be operated upon in the near future. The seventeenth patient has no obstructive symptoms, the prostate was normal on palpation and the patient is being followed closely for further developments. A diagnosis of carcinoma from an examination of smears was not rendered in 1 case histologically proved, and in 1 clinically evident case of cancer. In each of these the secretions were scanty and of a poor quality.

JOHN A. LOPEZ, M.D.

Blauert, J. E., and Emmett, J. L.: Transurethral Resection for Postoperative Urinary Retention. *J. Urol. Balt.* 1947 57 771.

When one is confronted with the usual case of urinary retention following surgical removal of the rectum and sigmoid it goes without saying that every means should be tried to establish normal micturition before transurethral resection is advised. When 3 or 4 weeks have elapsed after operation and the patient is still unable to void satisfactorily and a large residue remains, the problem demands more serious consideration. The surgeon must then decide whether to continue with indwelling or intermittent catheterization for several weeks or months hoping that vesical function will eventually be re-established, or whether to relieve the patient quickly of his trouble by transurethral resection. Because transurethral resection in these cases involves little or no risk to the patient causes no discomfort and

will eliminate the vesical dysfunction and residual urine promptly in well over 90 per cent of the cases, it is the authors' opinion that, when indicated, it should not be postponed longer than 4 weeks after operation unless the patient's general condition is not satisfactory. It is not necessary to perform a preliminary cystoscopic examination on the patient to decide if resection is indicated. Whether the condition is a simple contracture or fixation of the vesical neck or adenomatous hyperplasia, transurethral resection if completely done will eliminate the residual urine and establish normal micturition.

In the original paper on this subject, by Emmett and Cristol 33 cases were presented in which transurethral resection had been performed after operations on the rectum and sigmoid. These cases were encountered at the clinic in approximately a 10 year period which ended with January 1944.

The authors thought that it would be instructive to study this subject again by analyzing the cases in which transurethral resection had been done since the original report. Among other things they were interested in determining the approximate incidence of patients who came to transurethral resection following surgical removal of the rectosigmoid. Accordingly they reviewed the 34 cases in which the operation was performed during the 2 year period from January 1 1944 to January 1 1946 inclusive. These constitute approximately 3 per cent of the cases in which the rectum sigmoid or both were removed at the clinic during this period.

The largest number of operations performed on the rectum and sigmoid were one-stage combined abdominoperineal resections. None of the patients was less than 50 years of age, most of them were more than 60 years of age. At least 4 weeks were allowed to elapse in most cases. This was done for two reasons: first to allow the patient a sufficient time for recovery between the two operative procedures and second, to give the bladder a chance to re-establish its normal function spontaneously. The amount of tissue to be removed in most cases is rather small (15 gm. or less). The results of the transurethral resection in these cases are classified as follows: excellent, 30 fair 2 and poor 2. Contrary to general opinion good results in transurethral resection are not secured most easily in cases in which the patients have small prostates (weighing less than 10 gm.) but rather they are obtained when the prostates are of moderate size (weighing from 40 to 60 gm.)

Valério, A.: The Surgical Treatment of Hydrocele (Tratamento cirúrgico de certos hidroscies vaginais) *Brasil med.*, 1947 61 55.

In 1,468 cases of hydrocele of the testis or the spermatic cord the author employed injections of sclerosing substances. Under local anesthesia the contents of the hydrocele were aspirated and from 1 to 5 c.c. of Lugol's solution 90 per cent alcohol iodine solution phenol ether and iodoform, corrosive mercury of bicloride solution formalin quinoline

GENTOURINARY SURGERY

During the acute stage there is considerable edema of the mucous membrane of the bladder with a great tendency toward bleeding so the cystoscopic study is both difficult and ill advised. It is ill advised since the possibility of inducing an epididymitis is great. The characteristic picture in this stage is edema, and in 2 instances the patients were referred to the author because it was thought that they had bladder tumors.

In the subacute phase the characteristic lesion is an edematous plaque of plum colored mucosa. In the central portion of this area a slough develops and the central ulcer results. The trigone seldom seems to be involved in this stage but the ureteral orifices are frequently involved and this accounts for the not infrequent subepithelial round cell infiltration.

The healing stage occurs by the resolution of the frequent subepithelial round cell infiltration. The edematous areas and areas of inflammation or appears, in bladder shows areas of inflammation or appears, in the words of the author as though it had been splashed with small drops of red paint.

The use of novarsenobion is specific for this condition and the healing process under this therapy occupies less than a fortnight. There is apparently no residual scarring and almost immediately after the institution of this therapy the bladder becomes insensitive and the reduced vesical capacity rapidly increases.

The subjective signs of this condition are those of vesical irritation and reduced bladder capacity with pyuria and hematuria. The vesical pain is out of proportion to the degree of frequency. Fever, increased pulse and toxemia are notable by their absence.

In all the cases reported there had been a history of recent sexual contact and with the exception of 3 often had had a urethral discharge. The discharge was watery in character.

Nine cases of nonspecific epididymitis were reported and of this group 4 were treated with novarsenobion with immediate relief. The swelling subsided with great facility. ROBERT LICK, JR. M.D.

Goldstein A. E. and Rubin S. W. : Reiter's Disease followed by True Infective Abacterial Pyuria. *Brit. J. Urol.* 1947 19 33

The author reports a case of simultaneous Reiter's disease and infective abacterial pyuria.

There has been no etiological agent established for Reiter's disease with its triad of urethritis, arthritis and conjunctivitis. Nor has the etiological agent responsible for abacterial pyuria been determined although it has been shown repeatedly that the arsephenals are therapeutically specific.

The case presented was that of a 35 year old male who had a urethral discharge 8 days after sexual intercourse which was found not to be due to the gonococcus. Sulfonamides did not afford any relief and 3 weeks after the onset of the urethral discharge an incapacitating swelling of the right knee and

ankle was noted. A week later a purulent conjunctivitis developed. The latter cleared with penicillin and sulfonamide medication but the arthritic and urethral symptoms remained.

After 5 months the symptoms began to subside and at this time the patient claimed marked improvement. At this time the patient claimed marked improvement. At this time the patient claimed marked improvement. At this time the patient claimed marked improvement.

The physical examination demonstrated little urgency, frequency, nocturia, dysuria, and hematuria. The physical examination demonstrated little urgency, frequency, nocturia, dysuria, and hematuria. The physical examination demonstrated little urgency, frequency, nocturia, dysuria, and hematuria.

The urine examination was essentially normal except for pus blood and the presence of staphylococci on direct smear. Intravenous pyelography was without significant findings although both ureters were slightly dilated. Cystoscopy showed a markedly injected mucous membrane of the bladder particularly in the right and left anterolateral portions along with ureteral orifice dilatation. The kidney urines as obtained by ureteral catheters were found to be free of blood and pus.

The administration of 40 mgm of napharsen resulted in immediate symptomatic improvement and 2 additional injections were given at weekly intervals. The patient was asymptomatic during the 6 months prior to publication of the original article. The author briefly discusses the treatment of Reiter's disease and abacterial pyuria and reviews its etiological possibilities. ROBERT LICK, JR. M.D.

Adcock, J. D. and Plumb, R. T. Urinary Tract Infections. *J. Am. M. Ass.* 1947 133 579

Streptomycin has been shown to be effective in vitro against various gram negative bacilli frequently responsible for urinary infections which prove refractory to sulfonamide compounds and penicillin. The purposes of this article are (1) to report the results of streptomycin therapy in 21 patients with infections of the urinary tract due to gram negative bacilli which were sensitive to streptomycin in vitro (2) to correlate results of in vitro sensitivity and the concentrations of streptomycin in the patients' serum (3) to report the acquisition, in vivo of definite resistance to streptomycin.

The results of streptomycin therapy were most impressive in 5 patients with chronic infections due to organisms of the *Acetobacter* group. There was prompt relief of symptoms, pyuria disappeared, and urine cultures became sterile. These effects persisted after streptomycin therapy was discontinued.

The 5 cases in which in combination with other organisms, responded less satisfactorily. In each case pyuria diminished or disappeared with acute episodes rarely rapidly declined in the cases with acute episodes. The *Pseudomonas aeruginosa* was, however, constant ly present in urine cultures following therapy. In a case of chronic cystitis due to *Escherichia coli* temporary relief of symptoms and diminution of pyuria occurred but the bactericidal effect was obtained when the concentration of streptomycin in the serum

was approximately 10 or more times as great as that required for inhibition of the infecting organism *in vitro*. However the effect appeared to be merely bacteriostatic against the more resistant organisms in cases in which the sensitivity of the infecting organism more nearly approached the concentrations attained in the serum. The demonstration that the concentration of streptomycin in various tissues is far below that found in the serum may help to explain these relationships. Although streptomycin appears in the urine in high concentration it is doubtful that this is of importance in therapy since in an established infection there must certainly be invasion of tissue as well as infection of the urine itself.

Among the bacteria isolated following therapy three organisms apparently acquired an increased tolerance to streptomycin. In 1 case a strain of the *Pseudomonas aeruginosa* recovered just prior to therapy was inhibited *in vitro* by 4 mu gm of streptomycin while the strain isolated after 4 days of treatment required 200 mu gm for inhibition. In the same patient a strain of the *Streptococcus faecalis* which was initially present was inhibited by 20 mu gm but after 4 days of treatment it grew well in 1 mgm. Similarly a strain of the *Escherichia coli* was sensitive to 1 mu gm and after 5 days of treatment it grew in 1 mgm.

Should this phenomenon prove of frequent occurrence the size of the initial dose of streptomycin will be of extreme importance and if a bactericidal effect is to be obtained it must be obtained promptly.

G. EDWARD A. LLOYD, M.D.

Pool, T. L., and Cook, E. N.: Urinary Tract Infections. *J Am Med Ass* 94:7 33 194.

Two important factors must be considered in the management of infections of the urinary tract. The first is the coexistence of other pathologic processes in the urinary tract.

It was observed early that the presence of obstruction, tumor, stone or marked chronic inflammatory changes in the urinary tract definitely reduced the efficacy of the ketogenic diet in the eradication of urinary infection but when none of these pathologic processes were present the result of treatment with the ketogenic diet were much better. Exactly the same observations were made when mandelic acid, the sulfonamides, penicillin and streptomycin were used. The other factor is the variation in the results obtained with the various strains of organisms. This definitely suggests the importance of using various therapeutic compounds in alternate courses if one or another fails to eradicate the infection. Of course there is no use to do this if coexisting pathologic conditions have not been removed first of all.

For the routine treatment of infections of the urinary tract, mandelic acid and the sulfonamides are still the drugs of choice. Penicillin is a great adjunct to treatment but it has not been the boon we had hoped for in the ordinary case of non-specific infection of the urinary tract. Streptomycin produces spectacular results in some cases of resistant

urinary infection but cannot be used routinely at the present time. Our studies concerning this drug are incomplete because the supply has been so limited that it has been impossible to carry out the investigative work that should go along with the study of any antiseptic.

Donovan, H.: Care of the Urinary Tract in Paraplegic Patients. *Lancet* Lond., 947 53.

Donovan treated 82 paraplegic soldiers in a regional spinal unit. Almost all of them had had a high suprapubic cystostomy. The tubes were changed weekly. A No. 28 Malecot type connected to a leg bag is preferred. Tidal drainage was employed enthusiastically at first but the author concluded that the urines were more cloudy and pyrexial attacks were commoner with all methods of bladder drainage other than the direct simple one of leading the suprapubic tube into a bedside bottle.

After trying many solutions, the author settled upon a 5000 neutral proflavine solution as an emptying medium. The bacterial flora were constant, consisting of the *Bacillus coli*, *Streptococcus faecalis*, *Bacillus proteus* and *Pseudomonas pyocyanea*. It was found that penicillin was the best drug for reducing a pyrexial attack. Ammonium chloride (60 gr. daily) was the best routine urinary antiseptic, and the pH of the urine was kept at 5. Pyelography was carried out to exclude an obstructed upper urinary tract for unexplained fever lasting 3 days or more. During these attacks the urine from the bladder was almost always infected although it might have been clear to the naked eye.

A patient with an intact micturition center in the cord can often develop satisfactory automatic micturition with sufficient warning to enable him to dispense with an incontinence apparatus. When the bladder is closed the urine usually becomes much cleaner and the flora become simplified. Once the bladder has been satisfactorily closed pyrexial attacks may cease and the patient's morale is greatly improved. However, if he is completely bedridden, as with a low cervical lesion, nursing is easier with a suprapubic tube. In deciding whether the patient can achieve automatic micturition, the author looks for the following signs: (1) Does urine pass during bladder lavage or obstruction of the suprapubic tube? (2) Does the patient pass urine and empty the bladder during cystometrograms studies at any reasonably low pressure? (3) Do the muscles of the legs respond to faradism?

About one third of the patients developed calculi. In every case the renal tract was always roentgenographed every 3 months and an intake-output chart was kept. The patient's position was frequently changed, a high acid-ash diet was employed, and the urine was kept at a pH of 5 with ammonium chloride. In 30 per cent of the patients, renal or ureteral calculi were found. There was no apparent connection between the stone formation and the level of the paralysis. Recumbency was probably a major factor in causing stones and urinary tract infection.

GENITOURINARY SURGERY

was an important accessory cause. Stones were observed to form rapidly in a matter of weeks.

Cystometrograms were made but were not of great practical value as they did not show the site of the lesion or the degree of functional recovery. Excretory urograms demonstrated that no dilatation took place as long as the bladder was drained although dilatation of the upper tract is much more likely with cauda equina lesions than with spinal cord lesions. In the former the ureter can dilate extremely even after a few hours of retention.

DAVID ROSENBLUM, M.D.
J. Urol

Roth A. A.: Familial Eunuchoidism
Balt. 1947 57 447

The author studied 4 brothers who presented a marked hypogonadism on examination by the following tests: biopsy of the testes and mammary glands, x rays of the skull, frontal sinuses, and chest, excretory programs, assays of urinary gonadotropins and 17 ketosteroids, determinations of the blood cholesterol, blood urea nitrogen, glucose tolerance study and phosphorus, urinalysis, blood counts, study of the basal metabolism rates, and the blood pressure and Klinefelter's. Ophthalmological checks and psychometric studies were also carried out on each patient. The first patient was 55 years old. The outstanding findings in his case were infantile sex organs, retinal degeneration with rotatory nystagmus, unsteady gait with wide base and marked arthropathy of the left knee. The testes were small and microscopic studies showed the tubules to be small and papillated with Sertoli cells. Some tubules contained spermatocytes to severe in the tubules. The fibroblasts were increased. No Leydig cells were seen.

The second patient was 52 years old. He presented marked infantile sexual structures, retinal degeneration, rotatory nystagmus, scanning speech, and eunuchoid proportions. Testis biopsy was similar to

that of case 1. There were also hypoaesthetic reflexes and adiolococness of the right arm and asynergy major. The third patient was 49 years old and presented marked infantile sexual organs, extreme obesity, retinal degeneration with rotatory nystagmus, large breasts, generalized hypotonia, asynergy major and adiolococness of both arms. Testicular biopsy was similar to that of case 1. There were no germinal cells present, many tubules were completely hyalinized and no Leydig cells were seen.

The fourth patient was 47 years old and presented eunuchoid proportions, sexual infantilism, gait disturbance, and visual difficulties due to retinal pigmentation and rotatory nystagmus. Testicular biopsy was similar to that in case 1.

The appearance of the testes suggested that spermatogenesis had never occurred and this was interpreted as being due to a long standing lack of pituitary gonadotropins. The atrophic appearance could be secondary to failure of development from an infantile state.

The 17 ketosteroids in all 4 individuals were markedly diminished, as were the urinary gonadotropins. Cases 3 and 4 were treated for 40 days with chorionic gonadotropin and pituitary gonadotropin with no results and it was concluded that the testes were incapable of responding to such stimulation. All cases were treated with testosterone which resulted in increased pubic hair, voice change, increase in the size of the sexual organs and improvement in the gait and muscle tone.

The author concludes that long standing degeneration of the anterior pituitary gonadotropic hormones can produce gonadal failure and the resulting adipose genital dystrophy observed in these cases. In addition, there is probably partial adrenocortical failure secondary to lack of adrenotropin. The article includes remarks concerning the hereditary aspects of this so-called syndrome.

ROBERT O. BRADLEY, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Alarcón, F O : Penicillin and Osteomyelitis (Penicilina y Osteomielitis) *Rev As med. argent* 1947 6 5

The author believes that osteomyelitis and osteitis develop from inoculation via the blood stream, from an exogenous source or from a small contiguous infectious focus. He believes that penicillin has definitely lowered the mortality rate and the number of complications, but reserves his opinion regarding a total cure and the possibility of sterilizing a focus.

The doses should be large parentally and locally. If there is no tendency toward resorption of the sequestra resort to surgery is indicated. Abscesses should be drained.

Osteomyelitis is never cured if there is an elevated blood count and in chronic osteomyelitis, penicillin therapy should accompany the Orr treatment. Surgery should not be omitted when penicillin is used rather the latter is an auxiliary to surgery particularly when a compound fracture is present.

STEPHEN A. ZIEGLER, M.D.

Goesseco A. Von Recklinghausen's Generalized Osteitis Fibrosa Cystica and Epithelioma of the Breast. Difficulties of Diagnosis (Osteite fibro-géodique généralisée de Recklinghausen et épithélioma du sein). *Rev. chir. Par* 1946, 38 359.

Von Recklinghausen's disease treated and cured by parathyroidectomy is still sufficiently rare to warrant the presentation of a case of parathyroid osteitis associated with cancer of the breast.

A 38 year old female was admitted to the hospital with pathological fractures of both femurs and paralysis of the lower extremities associated with severe pain. The patient had pain first in the right leg, then in both legs and the right shoulder for the last 15 years. She consulted many physicians who treated her for rheumatism. Five years later she was forced to use a cane when walking. At that time a positive blood Wassermann reaction was discovered and for the following 2 years she received antisyphilitic treatment without effect on the pain in her bones. Ten years after the onset the patient was bedridden. She had to be hospitalized for 5 days because of a hepatic crisis. About a year later she sustained a fracture of both femurs associated with little pain. Six months later she sustained another spontaneous fracture of the right femur and soon afterward a fracture of the right clavicle. At this time there was complete lack of control of the lower extremities, generalized amyotrophy, and pronounced myasthenia. There were also old ununited fractures and recent fractures which were not accompanied by any

discomfort. Roentgenological examination showed generalized decalcification especially of the pelvis, spine, femora, and clavicle. There was some periosteal reaction in areas where the cortex seemed to have disappeared. There were cavities observed in the shafts and epiphyses of the long bones which gave the bones a polycystic appearance. The fracture fragments were overriding and there was no trace of repair.

There was slight hypotension, slight anemia, and a positive blood Wassermann reaction. The blood calcium ranged from 10.50/100 to 12.00/100 (Ward method), and the phosphatase was elevated to 900/100 (Janner Kay method). The urine calcium was somewhat above normal 0.46 per cent, and the phosphorus, 1.73 per cent. The Bence Jones albumin was negative.

There was hypertrophy of the thyroid, this organ being the size of half a lemon. Exploration of the area revealed a true enlargement of the gland. The hypertrophy of the thyroid gland dated back to the onset of the patient's skeletal complaints. The right breast showed a small scar the result of a biopsy about 6 months prior to the patient's admission to the hospital. The biopsy revealed an epithelioma. The regional lymph glands were not involved. The patient refused mastectomy at that time.

A diagnosis of generalized osteitis fibrosa cystica (von Recklinghausen) was made but the possibility of bony metastases from the epithelioma of the breast could not be ruled out definitely. It was therefore decided to perform a thyroidectomy. Histological examination of the excised right lobe showed masses of parathyroid cells imbedded in the thyroid tissue.

Twenty one months after the operation the general condition of the patient was greatly improved. There was gain in weight and the "bone pains" and anorexia completely disappeared. The pathological fractures were solidly healed but misaligned because of the fact that the patient removed the plaster casts after a month and a half. The X-ray examination showed considerable bone changes. The contour of the bones as well as their density was nearly normal. There was still some evidence of cysts in the shafts but the cysts were much less distinctly outlined. There was no change in the blood chemistry. The Chvostek sign was slightly positive, the Trousseau sign negative. There was regional glandular involvement of the breast cancer. Mastectomy was now performed.

GEORGE L. KIRBY, M.D.

Fossum, F : Roentgenological Considerations of a Rare Osteoarthropathic Syndrome (Considerazioni radiologiche su di una rara sindrome osteoartropatica). *Radiol. med. Milano*, 1947 35: 1.

The author reports a case of a female 47 years of age in whom symptoms of pain in the lower extremities started at the age of 11 and gradually became more manifest at the age of 16, when motion be-

SURGERY OF THE BONES JOINTS MUSCLES TENDONS

came limited. This pain was accentuated at the beginning of menstruation but was never accompanied by fever. At first the pain was more or less localized in the knee then it spread to the shoulder, elbow, wrist and feet in the given order. Within a year's time at the age of 21 the patient experienced ankylosis of all her joints and was not able to assume the erect posture eventually becoming bedridden. Pain at the beginning was great but it gradually diminished and finally disappeared while the ankylosis increased and spread to the feet, legs, and vertebral column.

The roentgenograms were characterized by numerous ankylosing foci of alterations of various sizes these were symmetrical osteolytic processes in the epiphyses and diaphyses. There was concentric atrophy in the region of the diaphyses and ankylosis of the large and small articular surfaces.

This condition must be differentiated from primary ankylosing chronic polyarthritis neurogenic osteopathies myelodysplastic localized cryptogenic foot (described by Kienboeck) localized cryptogenic osteolysis scleroderma Raynaud's disease the acromioclavicular and Blum's osteoarthritis pathic microstrophic.

ARTHUR F. CIPOLLA, M.D.

Umansky A. L. Schlesinger P. T., and Greenberg. B. B.: Tuberculous Dactylitis in the Adult. *Arch. Surg.* 1947 54 67.

Tuberculous dactylitis in the adult is a rare disease. It is relatively common in children. The disease involves the phalangeal bones of the hands. Because of its bony deformity it is called spina ventosa.

The authors' case report of a 19 year old negro is accompanied by 4 roentgenograms and an excellent clinical discussion. The patient was seen first by the authors in March 1941 with tuberculosis of the wrist. Two months later a fusiform, painless, progressive swelling of the finger in 1942 roentgenograms of the periosteum and cortical involved. Roentgenograms of the proximal phalanx of the left index finger soft tissue about the bone also showed an elevation of the proximal phalanx of the left index finger. A second roentgenogram of the proximal phalanx of the left index finger was taken in September 1943 because of persistent pain and swelling. This revealed rarefaction of the proximal phalanx of the left index finger with expansion of the bony cortex, or the so-called spina ventosa.

A fortnight later the patient reported for further observation. In addition to the previous roentgenologic manifestations alluded to, he had sustained a pathologic fracture of the affected finger. Despite the patient's condition he passed a month later examination, only to be discharged to the outpatient department. In 1944 he returned to the outpatient department where after a thorough examination the authors performed an amputation of his left index finger. Histologic examination revealed typical Langhans giant cells in the tubercle mass.

The differential diagnosis, according to the authors, should include (1) syphilitic dactylitis which is polystotic, (2) enchondromas (3) osteitis, (4) Boeck's sarcoïd (5) coccidioidomycosis (6) leprosy (7) yaws and (8) osteomyelitis.

Tuberculous dactylitis in children differs from that in the adult in that in the former the disease is concomitant with other organic disease, whereas in the latter the malady is not a part of a generalized process. Moreover fistula formation is the rule in children but no fistulas are found in adults. Amputation is the treatment of choice.

SAMUEL L. GOVERNALL, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Outland, T., and Corn O.: The Use of Parallel Grafts and of Two-Stage and Three-Stage Interlocking Grafts in the Treatment of Idiopathic Scoliosis. *End Results in 41 Cases.* *J Bone Surg.* 1947 29 103.

The greatest need in severe or progressive scoliosis is not a method of correction but the maintenance of the correction. In a large series of cases correction was attained in 61 per cent, but pseudarthrosis occurred in 28 per cent. Delayed fusion occurring after most of the correction has been lost is a problem which must also be solved. The authors present a method of fusion designed to improve the results in this regard for short curves (5 to 7 vertebrae) rigid tibial

For short curves (5 to 7 vertebrae) rigid tibial grafts are placed on both sides of the spinous processes. In longer curves the grafts are lapped at the middle to give maximum strength at that point (two-stage interlocking graft) For the very long fusions a three-stage interlocking graft is used. This is applied by putting the first graft along one side of the spinous processes the second graft on the other side and the third graft on the original side each graft overlapping by at least a vertebrae. The lateral articulations are not attacked but the grafts are laid subperiosteally against the spinous processes and laminae and the spinous processes are undercut and turned upside down to come into close contact with the graft.

Among the 41 cases of idiopathic scoliosis in this series there was no mortality and only 3 (7.3%) fractures of the graft occurred. One patient fractured the donor tibia and another developed a mild infection in the donor leg. There were other complications not related to the surgery.

The scoliosis with a double primary curve is disallowed. The authors favor correcting both curves as far as possible with a Risser jacket hinged at two levels. The thoracic curve is corrected first then the lumbar. The whole area is then fused.

The final results shown in the series presented (43% improvement) are much better than the results given by the Research Committee of the American Orthopedic Association (25% improvement). The authors warn against the danger of persistent conservative methods without accurate and frequent

measurements by means of x rays. These methods should certainly not be continued until a mild curve becomes moderate or severe.

The Risser jacket was the most effective method of correction of the severe curves. In a less severe case the Lemesuner hammock suspension afforded excellent correction.

Some good x rays and photographs are reproduced to illustrate the various points of this article.

Menzari A. Cure of the Postpoliomyelitic Flexion Adduction Deformity of the Hip (Sulla cura dell'anca flessa-abdotta poliomielitica). *Chir. org. modic.*, 946 30 383.

Three types of postpoliomyelitic contracture about the hip are described: the flexion adduction contracture, the surgical correction of which the author discusses; the flexion adduction contracture and the mixed forms of contracture. Of these the first is the most common. Most of the efforts to prevent the flexion adduction type of contracture with outward rotation at the hip and consequent obliquity of the pelvis to maintain the erect position of the body are rendered fruitless by the young child's habit of flexing the hip in sitting and walking on all fours. Other methods have been proposed to correct the paralysis of the adductors and flexors of the thigh. However no method has been devised against the outward rotation contracture and no method has been devised which tends to establish a functional counteraction against a possible recurrence of the original deformity. The author's method, which he believes to be original with himself, consists essentially in detaching the sartorius and tensor fasciae latae muscles at their proximal attachments and transferring them medially by means of subcutaneous tunneling to a new attachment on the pubic tubercle. Thus the sartorius becomes an adductor and the tensor fasciae latae muscle an inner rotator and after re-education they assume an active role in correcting the abnormality and guarding against recurrence.

The method has been employed by the author in 25 children from 7 to 14 years of age: the first time in 1934. Judging from the patients who were operated upon sufficiently long ago, the pelvofemoral position is found to have been corrected and there is no tendency toward recurrence. Both functionally and esthetically the author considers the results to be sufficiently encouraging to justify his reporting them at this time.

JOHN W. BRIDGES, M.D.

Murray C. R.: Treatment of Injuries to the Knee Joint. *A. England J. M.* 947 230 203.

Stabilization of the knee joint is accomplished not by various ligaments but by the co-ordinated action of the surrounding muscles. Any injury to the intra-articular portion of the knee joint is associated with a rapid hypotonia that is relatively selective for the extensor mechanism of the joint.

If examination, which should always be done with the thighs thoroughly exposed, shows there is no

visual palpable or measurable hypotonia or simply of the thigh, there is probably no lesion involving the knee joint and it can be assumed that the lesion lies outside of the joint. If there is hypotonia and atrophy of the thigh muscles soon after injury, the pathology lies within the joint.

Whenever a knee joint develops fluid within a matter of hours after injury, the condition is blemarthrosis and not traumatic synovitis.

Range of extension is a primary consideration. With the heel resting on the examiner's knee, the knee should completely extend. If it does not, muscle spasm or mechanical block is the cause. Spasm may be secondary to fluid in the joint.

Flexion due to spasm and fluid can be overcome by steady pressure, but on release of the pressure the knee rebounds into flexion. Normal knees do not rebound. If, because of the severity of pain or mechanical obstruction, the joint cannot be straightened, there is probably a mechanical derangement of the knee joint.

Spurting of the ligaments, when not accompanied by blemarthrosis, are not accompanied by rapid hypotonia and loss of thigh contour. If there are actual ligament tears they are evidenced by abnormal mobility of the joint in full extension.

Cruciate tears are less important than collateral ligament injuries. They rarely require surgical repair and should be treated by restoring the quadriceps mechanism.

The diagnostic feature of meniscus injury is a sudden, twisting effort, with the knee flexed, that results in localized pain on the inner or outer side of the joint, often followed by a sudden accumulation of fluid (blemarthrosis) and tenderness at the site of pain, and there may or may not be locking. A locked knee must be unlocked before it is immobilized. As manipulation should be done under an anesthetic, the method of reduction consists in first flexing the knee and hip to right angles. The tibia is rotated loosely inward and outward on the femur and then adducted and abducted. Following this the knee is brought into sudden extension.

The author believes in radical surgery if there are signs of a meniscus tear even if the joint is not locked. This should not be done for a first injury, however. Perfect results are not always obtained from surgery.

The patients with meniscus injuries in whom operation is not performed should be treated by placing the knee in an extension cast and made to walk without crutch or cane so as to develop the thigh by co-ordinated muscle activity. When this is not possible the quadriceps contraction exercise, a poor substitute, must be used. The cast is worn about 4 weeks, after which normal function is started. The patient is taught to forget flexion but to develop extensor power.

Immobilized joints become stiff because of a loss of elasticity and thickening of the capsular structures. This is the result of loss of minute circulatory efficiency due to absence of normal muscular activity. The joint does not have to move to remain healthy.

SURGERY OF THE BONES JOINTS MUSCLES TENDONS

but the muscles must be kept moving if the minute circulation of the part is to approach normal.

The author believes it is impracticable to make a clear cut and definite preoperative diagnosis in cases of internal derangement of the knee joint. He explores the joint thoroughly through a long incision without a tourniquet with the patient in a high Trendelenburg position. The parapatellar incision extends from the upper limit of the suprapatellar pouch to the tibial margin. Only 30 per cent of a series of 400 patients with internal derangements had meniscus injuries alone. Another 30 per cent had some other lesion such as torn crucial ligament or a synovial or fat pad lesion in addition.

Postoperative care is not complicated by the long incision. The joint is kept moving but no violent or forced exercises or exercises to fatigue muscles or beyond pain limits are permitted. Immobilizing the knee postoperatively may result in stiffness of the joint and should not be done. The more exercise undertaken by the muscles activating the knee joint within physiological limits the better off the patient when an injury to the meniscus and the joint is again under conservative treatment and the joint is again injured several months later the same conservative treatment is not repeated. A tear limited to the meniscus will never heal but it usually heals if it is in the ligamentous structures uniting the meniscus to the margin of the tibia. Recurrent injuries may be assumed to be tears through the cartilage which have not healed. Operative treatment is indicated. It is not wise to wait for multiple recurrences as these damage the articular surfaces.

Discussion of this article brought out several more points among them that the author routinely removes the fat pad when he operates upon mechanical ly deranged knees.

NEWTON C. MEAD, M D

Parker J.M. and Modlin J J Compound Injuries of the Knee Joint *Ann. Surg.* 1947 125 341

Early exploratory arthrotomy was found to be the treatment of choice in compound injuries of the knee joint. This observation is based on approximately 300 compound injuries of the knee joint treated in the Mediterranean and European theaters of operation. In the forward hospitals arthrotomy of the injured knee joints was carried out at the earliest possible time. Any intra-articular loose or foreign body was removed. The synovial membrane was closed. The soft parts were debrided but not sutured. Penicillin was administered intra-articularly and followed up by parenteral injections. The extremity was then immobilized in a hip spica or Tobruk plaster cast.

This article is chiefly concerned with the treatment of joint injuries at the base hospitals. The general condition of the patient is rapidly brought to a state in which further operative treatment is removed for the operating room the dressing is removed for the first time since its application. The uninfected knee will have diminished but painless motion. The pa-

tient is then anesthetized. Any excess intra-articular fluid is aspirated and cultured. Gentle irrigation of the joint cavity with saline solution is carried out. Should arthrotomy be indicated it should be carried out with the use of a tourniquet. Twenty thousand units of penicillin in from 10 to 30 c.c. of saline solution are instilled into the joint cavity. The skin is then closed.

The usual uncomplicated knee injury is immobilized with traction for from 5 to 7 days. Systemic administration of penicillin is continued. In cases with favorable response the intra-articular effusion per articular swelling and elevated temperatures disappear within 2 or 3 days. Early mobilization and exercises are very important in the after-care of clean wounds of the knee joint. Quadriceps atrophy and the formation of adhesions in the joint are prevented.

More than two-thirds of the injured knees were complicated by fractures of the condyles or the patella. Total patellectomy is indicated in severely comminuted fractures of the patella. In cases in which a major fragment with a good articular surface remains, it may be left *in situ* after excision of the smaller comminuted fragments.

Condyles usually show only minor fractures i.e. penetrating injuries chip fractures or incomplete fractures. Any muscle should be removed when at all possible. It may be hidden under portions of elastic cartilage which have retracted and in regularities of the condyles are smoothed down and loose fragments are removed. Severely comminuted fractures of the condyles are treated with skeletal traction or plaster immobilization to await solidification of the fragments. Fusion at a later date usually is necessary.

Loss of the soft parts around the joint often makes it impossible to approximate the wound edges. In cases in which the cartilaginous and bony portions of the joint are intact early plastic repair of the wound should be carried out. This can be accomplished by swinging a wide based pedicled flap over the defect or by shifting undercut adjacent skin over the soft tissue defect.

It was definitely established that compound injuries of the knee joint due to shell fragments showed a much higher degree of infection than those caused by bullets. Therefore even a highly shattered joint caused by a bullet should be treated conservatively since it is not likely to become infected.

Accurate data were compiled concerning 244 patients with compound injuries of the knee joint.

GEORGE I. REESE, M D

FRACTURES AND DISLOCATIONS

McCarroll H. R. I. The Use of Small Threaded Wires in the Treatment of Fractures Fractures of the Upper Extremities. *Arch. Surg.* 1947 54 154

The author advocates the use of the threaded wire in fractures of the clavicle dislocation of the acromioclavicular joint and fractures of the proximal end of

the humerus, particularly when the tuberosities are displaced. The surgical or the anatomic neck of the humerus may become badly displaced. As a rule open reduction may be carried out through a small incision anteriorly and adequate approximation of the two fractures can be maintained by the use of 2 threaded wires drilled through the tuberosity and into the medullary canal of the distal fragment. If there is any fear of the wire's wandering farther into the medullary canal this can be easily prevented by the application of a nut to the projecting portion of the threaded wire.

The wires are also used for fractures of the epicondyle of the humerus with displacement. These fractures usually require open reduction. The fragment is held firmly in place with a towel clip and a small threaded wire is drilled through the fragment and into the humerus. This affords excellent fixation. This wire is cut off flush with the surface of the epicondyle and is not removed. Plaster fixation of the extremity is necessary for from 6 to 8 weeks.

The wires are also useful in fractures of the olecranon. If such fractures are displaced open reduction is indicated. In this way the contour of the articular surface can be restored and the interposed periosteal flap, so frequently stripped from the cortex at the time of the fracture, can be removed which facilitates accurate reduction and apposition of the fragments. This is done through a small overlying incision the fragments are reduced and realigned exactly as in a jigsaw puzzle and are held firmly in place with a towel clip. A threaded wire is then drilled through the fragment and into the ulnar shaft.

In fractures through the neck of a metacarpal with angulation of the metacarpal head to the flexor surface a wire is passed through the distal fragment and into the medullary canal of the metacarpal, after accurate open reduction. A small incision is placed along one margin of the involved metacarpal. The wire is inserted through the distal fragment at the margin of the articular cartilage in order to disturb the structure of the joint as little as possible. In fractures of this nature the wire is always allowed to protrude and it is removed in 4 weeks. No external fixation is needed and this permits early institution of active and passive exercise in these hands, an all important factor in preserving function.

C. FRED GORDON, M.D.

McCarroll H. R.: The Use of Small Threaded Wires in the Treatment of Fractures. Fractures of the Lower Extremities. *Arch. Surg.* 947 54 35.

The author advocates the use of small threaded wires in the treatment of fractures of the lower extremities. Such a wire affords excellent fixation and it causes a minimum amount of trauma to the bone and soft tissues compared to other forms of internal fixation. Screws are too large for fixation of small fragments and often result in their comminution. The smooth Kirschner wire does not hold as well. The threaded wire combines the desirable features of the two and it is by far the most ideal aid

The Kirschner type of wire and traction bow has always seemed objectionable first, because the bow rested across the front of the leg below the knee and thus made it impossible to place the knee in complete extension when desired and second, because there was invariably a tendency for lateral play of the wire through the extremity and this resulted in some infections. Wires of this type and the bows from the leg lengthening apparatus were used for ordinary skeletal traction in many cases.

This method has been used over a period of 10 years for skeletal traction in several hundred cases. The method has proved satisfactory in every respect. With the threaded wire no tendency for the wire to wander has been encountered. When the wire is used for fixation of heavy cortical bone, however, as in transfixation of the fragments of spiral or oblique fractures of the long bones, it has been found that preliminary drilling of the wire tract is an essential step. Before this was learned an attempt was made to force the pointed threaded wire through these fragments of heavy cortical bone with a motor drill. It was found impossible to control the speed of the wire to make the rate of introduction correspond exactly to the number of threads per inch (8 s.c.) on the wire. In cortical bone preliminary drilling with an 0.070 inch drill point (No. 5 of the standard drill point gauge) for use of the $\frac{1}{8}$ inch threaded wire and a 0.067 inch drill point for the 0.066 inch wire insure solid fixation. The wire is simply drilled in for the required distance and cut off when desired. With preliminary drilling of this type, the hand drill is preferable and is always used both for the drilling and for the insertion of the wire. Pointing of the wire is not necessary. When used without preliminary drilling pointing of the wire is essential.

In the treatment of fractures of the malleoli, the author uses the threaded wire for fixation incorporating the blunt end of the wire and the plaster. Several weeks postoperatively the wire is readily removed. It has been utilized for spiral or oblique fractures of the long bones. For fractures of the tibia and fibula, threaded wires afford excellent fixation. These wires have also been used for similar fractures of the femur, but have proved entirely unsatisfactory. They will not withstand the force and strain to which they are subjected in a fracture of the shaft of the femur. For this fracture, simple skeletal traction is far superior and is preferable, as has been pointed out by many authors previously.

C. FRED GORDON, M.D.

Quigley T. B. and Urist, M. R.: Interphalangeal Joints. A Method of Digital Skeletal Traction Which Permits Active Motion. *Am. J. Surg.* 947 73 175.

Recent experience has re-emphasized the necessity for maintenance of active motion throughout the treatment of fractures of the metacarpals and phalanges. While anatomic reposition is desirable, traction is more dependent upon a minimum of splinting both as to extent and time than upon elimination of bony deformity. The relatively greater area of

joint surface and mechanisms in the small joints of the hand predisposes them to rapid development of stiffness.

Manipulative reduction maintained by various types of traction is often the treatment of choice although the usual means of traction prevent active motion. Common sites for traction in the finger are (1) the fingernail, (2) pulp of the distal phalanx, (3) the distal phalanx, (4) the middle phalanx, and (5) the proximal phalanx. All of the sites present disadvantages either with regard to the production of pain or possible damage to important structures.

On the dorsal surface of the middle phalanx there is a triangular space where only skin and fascia overlie the bone and this is a logical place for the insertion of skeletal traction. Through a stab wound the cortex is drilled at an angle of 45 degrees distally with a No. 6 dental burr. A hook fashioned from a Kirschner wire is engaged through this hole in the cortex and steadied by a small dressing. It is attached by rubber band traction to a banjo splint anchored in plaster. Active motion is insisted upon which, although not over a great range is sufficient to avoid freezing of the joints.

From experience with 70 fingers so treated it was found best to place the fingers in traction in flexion, as recommended by Bunnell. Mobilization is no more rapid than from the extended position, but the functional position permits use of the hand while mobility is being re-established. Traction is rarely maintained for more than 3 weeks. This method is best suited for fractures of the proximal interphalangeal joints, proximal phalanges, and unsupported metacarpals. Three cases are reported demonstrating use of the technique in compound comminuted fractures of the second, third, fourth and fifth metacarpals compound fractures of the third and fourth proximal phalanges and simple fracture of two-thirds of the distal articular surface of a proximal phalanx.

FRANCES E. BLENKES, M.D.

Oliver, V. B.: Epiphyseal Slipping of the Head of the Femur (Desprendimiento epifisario de la cabeza femoral). *Rev. esp. ort. cir.*, 1946, 3, 138.

The causes of epiphyseal slipping may be divided into three types: the purely traumatic, the static, and the type in which there is decreased resistance of the cartilage due to general or local causes.

The lesion is more frequent in the male but more pronounced in the female. The location is practically constant. Bilateral affection however is rare. The disease goes through three stages: a latent or prodromal period characterized by pain; a progressive period which leads to a solidification of the epiphysis to the neck of the femur and the formation of a coxa vara.

The most frequent complication is an aseptic necrosis of the femoral head.

Diagnosis presents some difficulties. Differential must be made from subcapital fracture and Perthes disease. Prognosis depends upon the severity of the disease process and early treatment.

Treatment depends upon the phase of the disease. In the prodromal stage traction abduction and internal rotation may be sufficient. Later intra-articular or extra-articular osteotomy must be resorted to before any practical results can be obtained.

STEPHEN A. ZIDMAN, M.D.

Boyd H. B. and George I. L.: Complications of Fractures of the Neck of the Femur. *J. Bone Surg.*, 1947, 29, 13.

The authors report a statistical study of 300 cases of fracture through the central portion of the neck of the femur operated upon by the staff of the Campbell Clinic. Smith Petersen nails were used in 285 of the hips and Knowles pins in 15. All impacted fractures and fractures of the base of the neck were excluded.

The postoperative follow up of 151 cases was less than 1 year on account of various factors such as distance from the Clinic, age, debility, lack of funds, and transportation difficulties. Twenty-eight of the patients died (Table I).

The report on bony union or nonunion is therefore based on 141 cases: in 122 (86.5%) union occurred and in 19 (13.5%) it did not occur (Table II).

Aseptic necrosis and degenerative changes of arthritis following bony union occurred in 33.6 per cent of the cases, but all cases of aseptic necrosis did not have arthritic changes, whereas a few cases without aseptic necrosis did have arthritic changes. Aseptic necrosis can be detected in the roentgenograms with in 1 or 2 years following fracture (Tables III and IV).

TABLE I — MORTALITY

Age	Number of hips	Deaths	
		Number	Per cent.
Under 40	13		
40-50	50		
50-60	92	5	5.4
70-79	37	9	24.3
80-90	55	14	25.0
Totals	300	8	2.7

Of the total number of deaths, 1 occurred in less than 4 weeks after operation, and 7 within 4 weeks to 6 months after operation.

TABLE II — BONY UNION

Age	Union		Non-Union	
	No. of hips	Per cent.	No. of hips	Per cent.
Under 40		100		
40-50	3	91.0	3	9
50-60	4	78		0
70-79	13	0		8
80 and older	1	33		
Totals		85.3	9	2.7

TABLE III.—CHANGES FOLLOWING UNION

Follow-up period	N of hips	Aseptic nonunion		Arthritic changes			
				Moderate		Severe	
		Number	Per cent	Number	Per cent	Number	Per cent
—2 years	31	10	32.3	3	9.7	6	19.4
Over 2 years	28		34		55.2		5
Totals	59	4	31.6	3	9	8	24.6

TABLE IV.—END RESULTS

	Per cent
Mortality	0.3
Poor End Result	
Non-union	3.5
Severe arthritic changes	4.0
Fair End Result	
Moderate arthritic changes	9.0
Good End Result	43.6
Total	100

The data presented in this article indicate that the total number of patients with severe arthritic changes in the hip will exceed the number with non union. In the future, the problem of rehabilitation and treatment of the patients with severe degenerative arthritic changes may become more important than the treatment of those with ununited fractures.

DANIEL H. LEVY, M.D.

Sherman, M. S., and Phemister D. B.: The Pathology of Ununited Fractures of the Neck of the Femur. *J Bone Surg* 947 20 9

Nine case histories are presented, some in abstract and others in detail. The essential factor in these cases was the ununited fracture of the neck of the femur. The original articles contain 42 figures showing roentgenograms and photomicrographs of the involved structures and discusses the findings, facts and theories of other investigators.

The incidence of nonunion is quite high in intra capsular fractures of the neck of the femur except in the cases which have been impacted or treated by accurate open or closed reduction and internal fixation. The factors responsible for this relatively high incidence are: death of the head fragment due to disruption of the blood vessels of the neck, displacement of the fragment ends, poor immobilization and failure of peripheral callus formation.

If the head fragment survives it undergoes atrophy to the same degree as the distal fragment. Treatment in this type of case is usually successful and extensive degenerative changes in the joint do not occur. If the blood supply to the proximal fragment is severed and the head dies, the head will appear to be more dense than the surrounding trophic living bone in the roentgenogram. There is slow invasion of the head by vascular fibrous tissue. The necrotic bone is absorbed and is replaced by cancellous new bone.

The necrotic articular cartilage remains unaltered until a new blood supply reaches it, at which time it is replaced either by an imperfect type of fibrocartilage or in part by bone. Transformation of a dead head takes place first at the margins of the fracture and the foramen. A pathological fracture between the dead and living portions may result in collapse and delayed union or nonunion. If union has occurred in the presence of a dead head and if weight bearing is begun before replacement is complete, the head will probably collapse and degenerative changes will be present on both sides of the joint. If the head is adequately protected, it may not collapse. The degenerative changes are minimal and a good functional result is obtained.

RICHARD J. BERNARD, Jr., M.D.

ORTHOPEDICS IN GENERAL

Lamas, A., Arnado, D., Celestino Da Costa, J.: The Blood Supply of Bone (La circulación de sangre en los huesos). *Press med.*, 946, No. 63 862.

This article is based on experiments on animals carried out in the laboratory organized by Reynaldo dos Santos. Studies on the blood supply of bone have been neglected somewhat although it is of great importance in the study of the physiology of bone. In spite of a number of attempts it was impossible to visualize a "bone artery" by means of arteriography. Hundreds of arteriograms were taken and several different methods were used, with the result that every artery in the soft parts was visualized but not a single "bone artery." Larger doses of contrast medium were used and serial roentgenograms were taken but without success.

Arterial therapy also shows different effects in infections of the soft parts as compared with infections of bone. The therapeutic effect of penicillin given in the arterial route was very good in cases of soft tissue infection but showed no results in infections of bone. The arterial route was used in 2 patients with a severe infection of the forearm and of the thoracic region and patients with osteomyelitis. After 3 or 4 intra arterial injections of from 15,000 to 20,000 Oxford units of penicillin the infection in the soft parts healed completely without surgical intervention. In the cases of osteomyelitis, however, there was no change in the disease in spite of the fact that much larger doses were used.

The analogy of the results of arteriography and arteriotherapy appeared significant. It was not the insufficiency of the blood supply in bone which explained these facts. Arteriograms of bones in the cadaver were unsuccessful unless the efferent vein was ligated (Lexter). It was found that there was a large arterial network in bone as well as "blood lakes" and these findings were confirmed by histological studies made by the authors. Another conclusion known but little emphasized is that blood does not spurt but only dribbles from a cut surface of bone; this has been frequently observed in amputations and trephine openings.

A search of the literature for an explanation of these observations was unsuccessful. Leriche in his

Treatise on the Physiology and Pathology of Bone stated that the circulation slows down when entering the bone. This slowing down should be brought in accord with physiological requirements. In addition to being a depot for calcium, bone has two functions one of support and the other of hematopoiesis. None of these functions requires an active circulation. The calcium metabolism is slow and it is regulated by glands of internal secretion. When the "bone is doing work," i.e. when the extremity is in motion, it is not subject to any change and there is no need for an increase in its blood supply such as observed in the adjacent muscles. Its function of support is of a static nature. It operates like a lever. There is no evidence of contraction like in a muscle. There is no evidence of sudden changes within the bone which would require an active circulation.

As far as hemopoiesis is concerned, a rather slow flow of blood is necessary this can be interrupted for short periods to allow young blood elements to enter the bloodstream at a rate dictated by the needs of the organism. In the spleen which has a similar function the circulation often comes to a standstill. The experiments of Kinsley and Husch show clearly that sphincters are placed at the entry and exit of every spleen sinus to stop the bloodflow in order to give the circulatory elements a chance to pass the vessel walls. All this indicates that the circulation actually slows down in bone, but it does not explain the ineffectiveness of arterial therapy and the inability to demonstrate the arteries in an arteriograph.

Carmine injected into the external iliac artery of a dog appeared in a soft tissue wound after 4 seconds in the skin after 7 seconds and on the cut surface of the bone marrow after 1 minute (it never appeared in the compact portion of the bone). The color of the dye was very pale in the bone marrow as compared with that in the skin. These experiments indicate that the circulation in bone is slower and that substances entering bone via the arteries get there in small quantities and become greatly diluted.

Histological studies show that the arteries in bone are constructed differently than arteries in the soft tissues. The nutrient artery of bone has a thick wall, thick intima, and a small lumen as compared with its size. Before entering the bone it describes a number of curves and then divides into two branches. Its ascending and descending branch supplies the bone marrow and probably some haversian canals. Finally it opens into the 'blood lakes' near the epiphysis. Large veins with very thin walls leave these blood lakes. These veins unite to form the vein which accompanies the nutrient artery. Its lumen is large as compared with the lumen of the nutrient artery. There are hardly any blood vessels in the periosteum of the diaphysis. The arteries lying in the haversian canal have a single endothelial layer of cells surrounded by a sparse layer of mesenchymal tissue.

The curves in the nutrient artery are responsible for the slowing down of the blood flow. A further slowing down of the blood stream is accomplished by the division into many branches. It loses its pulsating character and by the time it reaches the capillaries the blood flows slowly and evenly. The same happens if the blood is forced to run through collaterals but the pulsating character is lost much sooner.

There is another reason why there is no pulsation of the arteries in the bone. The arteries are enclosed in a rigid frame of compact bone. Physiological, pathological, or therapeutic vasodilatation cannot occur as it does in other tissues. Sympathectomy causes some changes in the arteries in the bone. The arteries of the bone have also an adventitia but it is quite dissimilar to the adventitia of the soft tissues. It is quite possible to prevent contraction of the artery in the bone but dilatation is very unlikely to occur. The narrow lumen of the nutrient artery admits only a small quantity of blood at a given time and the winding of the artery its division into numerous branches, and its course in a rigid frame make the blood circulate under low tension and without pulsation. In addition, it stagnates in the blood lakes and large veins. These facts explain why the arteries cannot be visualized on the arteriographs and why drugs placed in the blood stream have no appreciable therapeutic effect in case of infections of bone.

These observations do not clarify the physiological problems of bone but show them in a different light. It is quite likely that changes in bone attributed to ischemia are really due to blood stasis.

Some pathological conditions of bone need a great deal of blood which cannot be supplied by the bone arteries. The arteries are unable to dilate and to furnish the nourishment required by the lesion. In these cases the arteries of the surrounding soft parts multiply and hypertrophy. This happens very frequently in tumors. It is quite possible that bone tumors originate in the soft parts since bone is unable to furnish the necessary blood supply. Furthermore the arteries of the soft tissues are unable to perforate healthy compact bone to get to the tumor.

It is possible that the tumor originates in the periosteum or subperiosteal tissues and eventually invades the bone.

GEORGE L. REES, M.D.

Wolbach, S. B.: Vitamin A Deficiency and Excess in Relation to Skeletal Growth. *J Bone Surg* 1947 29 171

Deficiencies of vitamins A, C and D affect bone growth directly. Deficiency of vitamins A and D involve epiphyseal cartilage cell activities. Vitamin C deficiency in growing animals affects all collagenous structures. Vitamin A is unique in that when given in great excess it actually accelerates normal growth sequences. The acceleration bears quantitative relationships to the amount of vitamin A administered.

The deposition of bone by cells of the endosteum and periosteum is called appositional bone formation. The growth of membranous bones is entirely by appositional bone formation.

Endochondral bone formation sets the pace and the pattern of skeletal growth.

Vitamin C deficiency prevents bone formation by causing a failure of matrix formation specifically a failure in the synthesis of collagen. Administration of Vitamin C to guinea pigs totally deficient in this vitamin is followed by the prompt deposition of collagen and the formation of the matrices of connective tissue bone and teeth.

Vitamin D deficiency results in a failure of the bone matrix (osteoid) to calcify. Efficient concentrations of calcium and phosphorus ions in the blood plasma are not maintained.

The cytomorphosis of the cartilage cells is disturbed, in that they fail to complete the normal sequence which ends in degeneration and death. The epiphyseal cartilage accumulates. There is no ingrowth of capillaries to fill the spaces which normally result from the disappearance of cartilage cells. Administration of Vitamin D is rapidly followed by a resumption of cytomorphosis, extensive penetration of capillaries, and concurrent calcification of the adjacent matrix. Thus, in rickets two separate processes are involved. One is the failure of epiphyseal cartilage cells to complete the sequences of proliferation, maturation and degeneration and the other is the failure of matrices to calcify.

Hypervitaminosis-D as produced by the administration of excessive amounts of activated ergosterol leads to a great rise in serum calcium. If the alimentary source of calcium is not adequate calcium is obtained through the resorption of bone. The stoichiometry of blood calcium seems to have quantitative relations to the amount of vitamin D introduced. The maintenance of high calcium levels in rats through its use results in short bones with noncalcified trabeculae of unusual thickness and number at the diaphyseal ends, and resorption of cortical bone with noncalcified matrix deposition of periosteal and endosteal origin. By some authors this is regarded as a rachitic type of change.

Vitamin-A deficiency results in a cessation of all cellular sequences in the epiphyseal cartilage. Osteoclasts absorb the cartilage trabeculae which were calcified before the deficiency was established.

Dense calcification of the matrix of the diaphyseal border of the epiphyseal cartilage results in a thin plate of bone across the face of the epiphyseal disc. The cessation of bone growth is not accompanied by cessation of growth in other tissues, and in young experimental animals the central nervous system which grows, becomes paralyzed as the result of mechanical pressure within the skull which does not grow.

Remodeling of young bones ceases and appositional bone formation continues, which results in short thick bones. The appositional bone growth is in strict conformity to normal growth patterns until

inanition supervenes. The pressure on the nervous system is not due to excessive appositional bone growth.

Hypervitaminosis-A results in a great acceleration of all processes of growth which can be followed microscopically and specifically with regard to the epiphyseal cartilage sequences and in the resorption of bone and appositional bone formation necessary in the remodeling of bone in skeletal growth. Fractures are produced in from 6 to 10 days by the accelerated remodeling process. When large amounts of vitamin A are given, the linear growth rate of bone is retarded and there is a decrease in food consumption and growth of the animal (rat) as a whole. The larger the amounts of vitamin A administered, the greater is the retardation of growth and the greater is the rate and frequency of fractures.

There is no increase in the rate of multiplication of the cartilage cells, but there is an increased rate of growth maturation and death. The author concludes that some agent is released by this process which is responsible for the remodeling process of bone growth. He discards the explanation that it is a response to mechanical stimulation.

The description of the microscopic changes which are presented in considerable detail does not lend itself to condensation.

Fractures of long bones are easily accounted for by the extensive loss of previously formed cortical bone before the newly deposited bone has acquired strength. They occur at sites where remodeling is normal growth is most active. The new bone is set firm because its matrix has failed to mature or completely calcify.

A study of the ductless glands of animals with an excess of vitamin A revealed no demonstrable changes in the pituitary, thyroid, or parathyroid glands. Changes were seen in the adrenal glands, but their significance is not known for certain.

The dosages of Vitamin A in these experiments were tremendous, and were not compatible with life.

NEWTON C. MEAN, M.D.

Wietkower E.: Rehabilitation of the Limbless: A Surgical and Psychologic Study. *Corp. M.* 9:17 3 30.

This article well describes a useful approach to the limbless patient on the part of all those individuals who must deal with him.

The patient who has lost a limb naturally mourns his loss and must frankly show it or hide his grief behind a wall of psychological defense. Hence, he requires skillful handling of his depression based on understanding of its fundamental nature and not pity, praise, or a cheer up of man approach.

In a study of 200 amputees the following types of reaction were noted: 25 per cent showed persistent depression, over and above the transient depression experienced by the majority; 21 1/4 per cent became impatient, irritable, ill tempered and resentful no matter what was done for them, these patients remained dissatisfied and discontented full of resent-

ment toward the doctors the hospitals the government's provision for their care and even toward themselves, 5 1/2 per cent developed excessive anxiety about the future doubting their working capacity and the chance of making a living 21 3/4 per cent of the patients reacted to their disability with defiance, these individuals were uncommonly ambitious and were determined to make the best of a bad job. Some 14 of the 43 members of the last group showed cracks in the carefully built up facade by complaining of sleeplessness nightmares irritability trembling and crying fits.

Cheerfulness was the reaction characterizing 24 per cent of the patients and was very common in the early phases of the severely disabled. Genuine satisfaction over the loss of a limb in men who were thus exploited of a deep sense of guilt was rare. A few men were happy to pay such a price to get out of service. A small number showed no depression nor any protective measures against it.

The type of reaction depended upon a multiplicity of factors including the previous personality, the degree and site of the injury the functional efficiency of the artificial limb and the social and occupational situations. About 50 per cent of the patients studied were in a state of emotional maladjustment.

Vernon C. Turner, M D
 Industrial Injuries of the Back.
 Occup JI 1947 3 53.

Dickson divided the cases of backache seen in an industrial practice into four main classes according to their etiology.

1 The first group consisted of strain or rupture of the muscles or ligamentous structures of the lumbosacral area caused by overuse (fatigue), excessive lifting or direct trauma and the condition was characterized by lumbar muscle spasm localized tenderness over the affected region and limitation of back motion. The author believes that if the strain is severe enough the patient should be hospitalized immediately for bed rest traction manipulation under anesthesia injection of the trigger point with eucupin and procaine and graduated exercises.

2 The second group presented arthritis of the lumbosacral joint. In this condition there are proliferative changes about the small joints and in elasticity of the ligaments. It is characterized clinically by (a) persistent dull aching low in the back, made worse by back motions (b) limitation of motion of the lumbar spine (c) referred pain usually into the hips and lower abdomen and (d) roentgenologic evidence of joint change in the spine. Ankylosing arthritis of the spine must be differentiated from hypertrophic or traumatic arthritis. It is characterized by increase of pain on rest rather than activity by a "poker back" by occurring in a younger age group and by roentgen evidence of involvement of the sacroiliac joints as well as of the spine (in a later stage).

Treatment consists of bed rest traction physical therapy exercise and possibly a back support.

3 This group consisted of sprains and subluxations of the sacroiliac joint. Dickson finds this to be a very rare condition which is characterized by pain and tenderness directly over one or the other sacroiliac joint a roentgenogram will show actual separation of the joint.

Treatment consists of bed rest with strapping and later a specially designed belt.

Sprains and subluxations of the lumbosacral joints are also included in the third group. These are the most frequent causes of back pain (other than arthritis) because of the frequency with which congenital abnormalities which weaken the joint decrease its stability and render it vulnerable to injury are found.

4 The author believes that cases of protruded intervertebral disc complicating a previous weakness low in the back should have the benefit of exploration for the ruptured disc, its removal and spinal fusion. The case of uncomplicated intervertebral disc should be subjected to excision of the ruptured disc, but no fusion.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Christophe, L., and Honoré, D.: Arteriography by Injection and Automatic Taking of Negatives (L'artériographie par injection et prise de clichés automatiques) / *chir* Par 947 63 5.

Increasing need for arteriography not only in brain surgery but also in surgery of the extremities induced the authors to invent an arteriographic apparatus. The apparatus, which appears complicated at first sight, can be operated by simple pressure of a finger on an electric button with the resultant intra-arterial injection of a negative taken at the moment of production of a contrast medium, has been discarded because (1) certain autopsies revealed microscopic hemorrhages in the brain due to this medium (2) demerol substances are capable of causing delayed sarcomatous new growths, this having been observed after a single injection of 30 c.c. of thorotrast and (3) thorotrast is manufactured by factories now in the Russian zone and therefore they were unobtainable until after the end of the war. In place of thorotrast the authors use umbradil, which consistently gives good results and is entirely innocuous.

The apparatus permits the injection of very variable amounts of contrast fluid at rates equally as variable. Three cubic centimeters can be injected in 10 seconds or 30 c.c. can be injected in 1 second. This adaptability of the apparatus permits the authors to use it not only for arteriography of the brain but also for arteriography of the aorta and of the arteries of the extremities. After aortography when the authors are assured of the permeability of the iliac and crural arteries, a second injection into the femoral artery is made and a complete arteriogram of the lower extremity is obtained. Three exposures,

one each of the thigh, leg and foot, are made after one injection of the femoral artery.

The authors have come to use arteriography almost routinely on their surgical service. They use it especially in the study of the sequelae of serious brain trauma, in which cases epidural and subdural hematomas can be localized. It is used, also, in the treatment of diseases causing obliteration of the arteries. Systematic preoperative roentgenologic study of the peripheral arteries in cases of arteria permits the selection of an operative procedure and aids in the prognosis in this uncertain and inoperable affection.

Description of the apparatus. The apparatus is composed of a mechanism for injection and a system of automatic contacts.

In the injection mechanism (Fig. 1) an electric motor (A) pushes a metallic bar (B) at a variable speed by means of a circular ratchet, a metallic bar (B) and the extremities of the bar press upon the piston of a syringe (C). The progression of the bar assures the injection. The volume and the weight produced by the electric motor (A) are required for easy manipulation of the apparatus. The authors have been completely satisfied with a small motor of 22 volts, continuous, supported by a rectifier mechanism in the system.

The speed of the motor regulated by a brake (E) permits more or less rapid injection, according to the artery to be examined and the affection suspected. In order to allow easy manipulation of the bar of propulsion (for example at the moment of refilling the syringe) the cogged wheel, which sets the ratchet in motion can be disengaged by means of a lever (F). At the moment when the apparatus is in use, the lever is brought down the cogged wheel engages, and the apparatus is ready to function. The apparatus has, in addition, been improved by the use of the action of a magnet (G). A core of soft iron (H) attached to the end of the propulsion bar enters into

Fig. (Christophe)

Fig 2 (Christophe)

the field of this magnet at the time of the injection. It brings about the disengagement of the ratchet, avoids wear and tear and prevents reflux in the syringe.

The entire apparatus is mounted (Fig 2) on a hinged bracket fixable to the roentgenographic table. It can be brought very near to the body of the patient.

The automatic release of the roentgen tube is composed of a slide contact placed parallel to the propulsion bar. The slide contact supports two platinum terminals which are separated from one another by a spring.

At the time of functioning the stop (L) comes in contact with the slide contact releases the spring closes the circuit in the two terminals throws the roentgenographic apparatus.

It is necessary that the slide contact be mobile in order that the negative can be taken at the exact moment of injection.

Operation of the apparatus

- 1 The electric circuit is checked
- 2 The speed of the motor is regulated according to the caliber of the needle and the speed of injection desired.
- 3 The opportune moment for taking the negative is calculated. The slide contact is placed opposite the number of cubic centimeters which are to be injected.
- 4 The full syringe is put in place
- 5 The propulsion bar is placed in contact with the cogged wheel.

The apparatus is ready for use

BLACKWELL MARRIAM, M.D.

Stewart, C. F.: War Experiences with the Nonsuture Technique of Anastomosis in Primary Arterial Injuries. *Ann. Surg.* 1947 125 137

This article is concerned with the problem of restoring blood flow through arteries damaged by missiles. Seven cases of gunshot or shell fragment wounds of major arteries are presented. These were representative vascular injuries, demonstrating division of the artery in 3 cases, thrombosis in 2 and lateral laceration in 2. The author describes the use of a vitallium tube lined with a vein segment which overlapped the ends of the tube. This is the method that was used in the cases that are presented. In all of these vessels a nonsuture anastomosis was attempted with varying results. The limbs of 3 of the patients survived. This makes a survival of 43 per cent in this group.

The author notes that it is futile to compare statistics in so small a series and adds a record of the results of the major vascular surgery in the first half of 1945. Inclusion of the prosthesis cases in the statistics during this period raises the survival of limbs in cases of superficial femoral artery from 57 to 63 per cent. In the statistics for the brachial artery this survival falls from 88 to 78 per cent with failure in 1 prosthesis case. The statistics show that survival in the popliteal group rises from 0 to 11 per cent.

A discussion of technical difficulties and of possible improvements is given.

The author concludes the article by outlining the ideal treatment of a case with a lacerated divided or thrombosed artery as follows

Preoperative treatment

- 1 Shock treatment morphine to allay pain transfusions with proper type of blood to restore the blood volume

2 Propylactic treatment antitetanic toxoid or serum with polyvalent gas gangrene serum if the conditions indicate it.

3. A sympathetic nerve block should be done on the affected side.

Operation

1 Wide and thorough débridement of the wound

2 Clean isolation of the vessels involved and temporary local occlusion of the artery with rubber guarded clamps.

3 A cursory examination of the collateral circulation, which will give an idea of its ability to support the limb.

4. Preparation of the prosthesis: adequate size from the adjacent vein: it must be reversed and one end kept marked

5 Débridement of the ends of the artery and periarial stripping 1 inch away from the divided ends.

6 Removal of all clots from the vessel ends and irrigation of them with a heparin-saline solution.

7 Insertion of the largest sized prosthesis that can be used, the procedure being started with the upper end of the artery and the upper clamp released to be sure that the flow passes through the prosthesis.

8. Firm double ligation of the arterial ends over the prosthesis with heavy silk.

9. Release of the occluding clamps.

10. Closure of the vascular sheath and wound when ever possible.

11 Local block of the nerves of the involved limb

Postoperative care

1 The blood volume should be kept up with whole blood transfusions as indicated.

2 Penicillin or chemotherapy should be continued.

3 The patient should be heparinized by subcutaneous injections of the drug in Pitkin's menstruum.

4. Reported nerve blocks should be given as long as the state of the circulation is in doubt.

5 The extremity should be splinted in a neutral position for from 10 to 14 days.

6 The limb should be maintained at a subnormal temperature.

HAROLD F. THURSTON M.D.

BLOOD TRANSFUSION

TOURNIAIN, L. M.: The Mechanism of Hemostasis.

Ann. Surg. 1947 35 29

This is an expository review of the existing knowledge of blood and vascular physiology, particularly integrating some of the facts that have been brought out during the past 5 years. Petit was among the first to call attention to the significance, in the spontaneous arrest of bleeding from wounds, of the plugging mass formed within and just outside of the opening of divided vessels.

In recent years, research and discussion on the mechanism of hemostasis and its disorders have been chiefly concerned with the coagulation of blood and the properties of the clot. The spontaneous arrest of bleeding involves more factors than those contributed by the blood alone. After a given injury the amount of bleeding will vary according to the pro-

viding efficacy of the hemostatic mechanism in the involved area. Moreover factors which contribute to the continuation of bleeding in one section of the body may have a negligible influence in another.

At least three groups of factors may be said to be engaged in preventing or checking blood loss from the body: (1) extravascular factors, (2) vascular factors, and (3) intravascular factors.

EXTRAVASCULAR FACTORS

Location of the vessel. If the vessel runs close to the surface with little or no tissue intervening between the vessel and the air it is at some disadvantage insofar as hemostasis is concerned. This is particularly true in nasal bleeding. The small vessels coursing along the mucous or serous surface of the gastrointestinal respiratory or urogenital tract, or of any other hollow viscera are likewise deprived of such support: therefore much blood may be lost.

Tissue tension or elasticity. Tension in the tissue surrounding the vessel wall protects it from damage and aids in resisting the flow of blood through the damaged site. The elasticity of the skin is thus an important factor in small cuts. In the aged elasticity is lacking. Vessels coursing through bone, ligaments, cartilage, or other semirigid structures are well protected from injury because of the rigid support about them. The noncollapsible character of the tissue about such vessels may however delay hemostasis when the rigid channel through which the vessels run is destroyed.

The resistance offered by the tissues of the body to forcible distention varies, of course with the type of tissue. This resistance is known to oppose the loss of fluid from vessels, and it also influences the escape of blood from them. The tissues of certain organs, like the brain, offer little resistance to blood extravasations. Whenever loose areolar tissue surrounds a vessel, it affords little resistance to extravasated blood. Scleroderma is just the opposite.

The content of thromboplastic substances in the tissues may conceivably have some influence on the rapidity of the clotting of blood escaped from the vessels. Anticoagulant materials are also found in the tissues in varying concentration and potency apparently aided by side with thromboplastic substances. Tissue autolysis will often destroy the clot accelerating substances.

VASCULAR FACTORS

Structure of the vessel. This is principally related to the essential difference between arteries and veins as to elasticity and muscular tissue as well as to their relative sizes and the pressure within. The state of relaxation or spasm as a related factor is severance is of the greatest importance.

INTRAVASCULAR FACTORS

The hemostatic plug. This plug may consist of platelets alone, fibrin, white cells, red cells, or all in combination. Arrest of bleeding depends in a large measure on the formation of this plug by elements

from the blood itself. Formation of the plug may be separated into three phases each of which may occur independent of the other or fail to appear altogether. These phases are (1) platelet massing (2) deposition of fibrin and (3) contraction and hardening of the platelet/fibrin plug. Platelets from the blood are attracted to the damaged zone come together, and adhere to and form a layer over the area. This is probably the simplest form of reaction of the blood to an injury of the vessel wall. It may be the only form of reaction to injury in small vessels when the blood pressure and volume are relatively low and the vessel walls thin and collapsible. When the platelets come together they may swell burst and liberate substances with clot accelerating properties. A thin fibrin film may then be deposited at the point of contact between the platelet mass and the overlying blood. Other platelets then adhere to the film and form clumps. Platelet massing requires that there be an adequate supply of platelets with the proper degree of agglutination ability and capacity for adhesion. The number of platelets in the peripheral circulation depends somewhat on the rate of production, the rate of utilization or destruction, and their distribution in the body. The platelets originate from megakaryocytes found principally in the bone marrow. The normal rate of production is probably 100,000 platelets per cubic centimeter of blood per day. This is accelerated after hemorrhage.

Platelet utilization and destruction are intimately linked, since when the platelet is used it is nearly always destroyed. Generally the utilization of platelets increases whenever the body is exposed to excessive stresses. The reverse takes place when the illness is over. The distribution of platelets is not uniform throughout the vessels and more are found in the arterial than in the venous blood of the extremities.

In vessels in which the pressure or volume of blood is high much of the effectiveness of the hemostatic mechanism depends on the rapidity with which the fibrin clot will form and the promptness with which the clot will become dense, adhere to the vessel wall and retract itself.

Fluidity and coagulability of the blood are antagonistic to one another. It is by keeping a balance between the fluidity inducing (anticoagulant) and coagulation promoting (coagulant) factors that the blood maintains itself as a circulating medium. These factors are well known. The changes that occur in the blood after it is shed and brought into contact with foreign surfaces present three phases.

First phase: release of cephalin and reduction and eventual loss of the natural anticephalin activity of the blood when it comes in contact with the released cephalin or the damaged surface of the vessel. The normal slowly reacting prothrombin is made highly vulnerable to the action of cephalin. There is no particular order of these steps.

Second phase: transformation of prothrombin to thrombin. This depends on the amount of cephalin available and the extent of the anticephalin activity

Third phase: Action of the thrombin on the fibrinogen with the production of fibrin. The clot is eventually liquefied by the action of fibrinolysin.

As long as the contacting surface of the interior of the blood vessel (endothelium) is intact, the stability of circulating blood will be unaltered. When the surface is damaged the stability is threatened by the presence of cephalin rich tissue juices which help to neutralize the blood anticephalin activity and to accelerate the conversion of prothrombin to thrombin, and the changes in the physical properties of the surface in contact with the blood. The damaged surface helps to remove anticephalin from the blood and aids in the disintegration of platelets and leucocytes with the consequent release of more cephalin from the platelets.

The term cephalin serves to designate the lipid or group of lipids with clot accelerating properties which form the active component of thromboplastic tissue and platelet extracts. It is found especially in the brain, lung, heart, and testicle. In the blood itself it is found chiefly in the platelets and leucocytes. On disintegration, platelets release cephalin; this is thereby dispersed through the blood and initiates the changes in the immediately neighboring areas which eventually lead to the formation of thrombin. The number in the blood is about 40 times that required to accelerate the coagulation of normal blood. Platelet disintegration however is the important factor. The two most important factors that influence platelet disintegration are the coagulability of the plasma in which the platelets are suspended and the extent of contact with surfaces favoring their disintegration.

When suspensions of human cephalin or cephalin containing substances are incubated with normal human plasma in plastic or collodion coated tubes, their clot accelerating power is greatly reduced. This property is termed anticephalin activity. Little is known regarding the nature, source and mode of regulation of this activity.

Prothrombin is a protein with many of the characteristics of the globulins, and is probably the clotting factor about which the greatest amount of information is available. The amount of prothrombin ranges between 5 and 10 times the amount required to bring about prompt coagulation of the blood. Other factors being equal a diminution to about 10 per cent of the normal, or less, is necessary before a significant change is observed in the rate of clotting and the quality of the clots formed. This diminution may result from the increased utilization as after widespread trauma or long illness, the imperfect synthesis of prothrombin by the liver, improper digestion or absorption of an otherwise inadequate diet, deficient intake of vitamin K, the effect of certain drugs or from vascular or congenital idiopathic hypoprothrombinemia.

Fibrinogen is the blood protein which when acted upon by thrombin is transformed into fibrin. It is principally formed in the liver. From 180 to 400 mgm. per 100 ml. is the normal range.

Fibrinolytic is an agent which brings about dissolution of the fibrin formed during coagulation. It probably exists in the plasma in the form of pro-fibrinolytic and requires activation.

Antithrombin offsets the action of thrombin. The activity appears to reside in the albumin fraction of the plasma or a constituent closely associated with that fraction. The union of thrombin and this albumin constituent leads to the formation of meta-thrombin, an inert product insofar as clotting is concerned.

In order to be effective the hemostatic plug must be formed promptly and meet certain requirements. Desirable attributes are adhesiveness, rigidity and contractility. Generally speaking the faster the blood will clot, the more rapidly will it develop the desirable physical attributes.

THE DYNAMICS OF HEMOSTASIS

The spontaneous arrest of bleeding nearly always involves two phases which take place regardless of the type of vessel involved.

First phase (vascular) Immediately after blood begins to escape from a vessel the pressure drops, the vessel walls contract, retract, or collapse and if the blood is escaping into the tissues, the surrounding tissue tension increases. The blood is then rerouted through another vessel.

Second phase (hematogenous) The relative slowing of blood flow during the first stage affords it the chance of coming into contact with extravascular tissues or the damaged vessel wall and precipitates the changes which lead to the plugging of the lacerated area. The longer the first phase lasts, the greater the chance for these changes to take place.

The order of succession, duration and magnitude of the changes included in these two phases varies considerably according to the type, caliber and location of the vessel or vessels, involved and the volume, pressure, and other properties of the blood within. Arterial blood of the systemic circulation seems to have a higher platelet content than venous blood. This favors the highest level of hemostasis in arterial blood, but is offset by the higher pressure and rate of flow.

Another variable introduced by the changing caliber of the vessels is that the rate of clotting of a

given mass of blood varies inversely to the extent of the surface in contact with the blood. Generally speaking the greater the surface in contact with a given amount of blood, the faster the coagulation. Likewise the chances for adhesion of the clot are greater if the blood is spread over a large surface. This reaction should be most effective in small vessels.

The structure of the vessel and the pressure of the blood within it determine to a great extent the relative importance of each of the hemostatic factors. In arteries, with blood pressures of from 100 to 120 mm. Hg. and arterioles from 60 to 70 mm. Hg. the factors, in order are vascular contraction and retraction, formation of the hemostatic plug, external compression and platelet massing. In capillaries, with blood pressures from 30 to 40 mm. Hg. and venules, from 10 to 20 mm. Hg. the factors, in order of importance, are external compression, platelet massing, vascular contraction, and formation of the hemostatic plug. In veins, with pressures from 0 to 10 mm. Hg., the factors, in order are platelet massing, external compression, formation of the hemostatic plug and vascular contraction.

A few general deductions are:

1. The nature of the defect determines to a large extent what vessels will be affected and these, in turn, determine the location and type of hemorrhagic manifestations.

2. Failure of spontaneous hemostasis may not necessarily follow a deficiency or absence of any one, or even two, of the factors named, provided the existing stresses are moderate and exerted chiefly on vessels not wholly dependent on these factors to check the flow of blood.

3. Most methods of securing hemostasis are attempts to duplicate in one way or another the principal steps of the natural mechanism of hemostasis, namely (a) external compression by the use of dressings, packs, distensible bags, and other devices; (b) contraction and retraction of the vascular wall with ligatures, clamps, forceps, or certain drugs like epinephrine; and (c) formation of the hemostatic plug by supplying or aiding the body to produce prothrombin, fibrinogen, platelets, or other constituents that it may lack.

LEROT J. KLEINSMITH, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Owens N: Implantation of Fascial Strips through the Masseter Muscle for Surgical Correction of Facial Paralysis. *Plast Reconstr Surg* 2: 1937: 25

Facial paralysis presents a psychological as well as a physical condition. The imbalance of the facial muscles results in great distortion on any attempt at expression.

Psychologically inferiority complexes and morose dispositions frequently develop. Injuries to the facial nerve, either accidentally or due to radical surgical procedures are increasing. Many operative procedures have been attempted to offer relief in these cases. Two fundamental procedures remain—muscle transplants and support by fascial strips.

The literature is reviewed in detail. The purpose of surgical intervention is twofold: to give support

Fig. 1 (Owens) a, Drawing showing some of the important muscles of expression. b, Drawing showing the sites of the 4 skin incisions utilized in this operation.

Fig. 2

Fig. 3

to the involved side of the face, and to offer reanimation. To secure these objectives muscle pull must be associated with the supportive features. The use of the masseter muscle is indicated since it is powerful and close to the paralyzed muscles (Fig. 1).

Fascia lata strips about 25 cm. long and 1 cm. wide are formed into loops. Three loops are used. An incision is made exposing the masseter muscle and this is connected by tunneling with a small incision in the upper lip past the midline on the unaffected side, a small incision in the lower lip past the midline on the unaffected side, and an incision at the corner of the mouth on the affected side. The free ends of each loop are passed from the smaller incisions subcutaneously to the incision over the masseter. Then one free end of each loop is passed through the body of the masseter muscle. The ends of the loop are drawn taut to elevate the lip and angle of the mouth about 1 1/4 cm. The fascial loop is knotted and securely fixed into position by interrupted No. 30 white cotton sutures. The skin wounds are closed. Support to the lip for from 16 to 21 days is given by gauze strips fixed with collodion (Figs. 2 and 3).

A report of 21 operations for facial paralysis is given. The author states "The operation which offers support and reanimation in cases of facial paralysis by means of fascial strips which connect paralyzed muscles with a functioning masseter muscle is the operation of choice."

EARL H. KLASUNDE, M D

Cummine H: Postoperative Thrombosis and the Blood Coagulation Times. *Med J Australia* 1947 1 302.

The author points out that spontaneous intravascular thrombosis may occur not only after operation when it stands out as a separate entity but also in diverse medical conditions in which it is frequently masked completely by the primary disorder.

The history of anticoagulant therapy is reviewed beginning with Murray's report on the use of heparin in 1940. Heparin which appears to be an antiproteinase and an antithrombin has an immediate action in prolonging the coagulation time. In the author's hands, the only reliable method of administration was by the intravenous route with the object of maintaining the coagulation time between 10 and 15 minutes.

Dicoumarol inhibits prothrombin formation by the liver. Its effect may not be apparent for 24 hours, and the dose is regulated by a daily determination of the prothrombin index, the object aimed at being 50%. Its greatest advantage is that it can be administered orally. Ideal therapy consists in the combination of both anticoagulant drugs.

Early signs and symptoms of thrombosis are rise in the pulse rate and temperature, muscle cramps in the calf and retrosternal oppression or chest pain. Early postoperative ambulation, bed exercises, and deep breathing are valuable prophylactic measures.

The writer has confirmed the observations of Bergquist of Copenhagen who established the use of

the postoperative coagulation graph. Bergquist found that in the cases in which intravascular thrombosis subsequently developed, the coagulation time came down and remained at 3 minutes for a period of hours before the onset of clinical signs or symptoms, and that the intravenous use of heparin at this stage prevented the onset of the condition. The capillary tube method for estimating the coagulation time is recommended.

The blood coagulation time varies from hour to hour and day to day so that the graph resembles an undulating curve. An isolated reading of 3 minutes or less frequently occurs and is of no significance, but fixing of the reading at this low level is suggestive of developing thrombophlebitis or pulmonary embolism.

The author treated 16 patients with pulmonary embolism, none of whom died. In these cases, heparin was either administered intermittently at 4 hour intervals or introduced through the rubber tubing of a continuous intravenous drip apparatus when required. The coagulation time was kept between 10 and 30 minutes and as near to 15 as possible. It was rarely necessary to administer heparin longer than a few days. There were no instances of hemorrhage or idiosyncrasy due to heparin.

Active motion, bed movements, and deep breathing exercises were instituted as adjuncts to heparin. Ambulation as early as possible was practiced. Massage was forbidden. Penicillin was given continuously to prevent superadded infection.

Dicoumarol was used in conjunction with heparin in some cases. In 1 case, melena, hematemesis, and wound hemorrhage developed with a prothrombin index of 30 per cent. An index of 50 per cent is probably more satisfactory. The coagulation graph is not affected by the administration of dicoumarol.

Serial electrocardiographic tracings were made in most cases, as it was found that a single tracing is of diagnostic value in only a small percentage of cases. The electrocardiogram may lend valuable confirmatory evidence or may be of no diagnostic value.

Chest x-rays may reveal an area of pulmonary infarction immediately. Other roentgenologic pictures may reveal frank consolidation, pleurisy with effusion, dilatation of the pulmonary cones, enlarged right heart, and increased hilar shadows. Very often the x-ray offers little help.

No significant changes in the leukocyte count or blood platelet count were noted.

S. LYON TRITTMAN, M D.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Chidichimo, G.: The Spontaneous Evolution of Felons—Treatment with a Closed Method without Intervention (Evolutione spontanea del piodroma—Trattamento di un metodo chiuso) con o senza intervento. *Pediatrics*, Chir., 1947 54 19.

In a study of 70 cases of felons and phlegmons of the hand, treated by immobilization for from 1

days in a plaster cast by surgical incision and then the application of a cast or by primary immobilization and then incision, followed by a new application of plaster the author has noted the beneficial effect of immobilization in all of the cases. A cure of the superficial felons was obtained after 8 or 10 days. In the deep infections the infective process became circumscribed with diminution of pain, and sometimes a spontaneous opening with elimination of a necrotic core or bone sequestra occurred and the fever was dissipated.

Using a similar method of treatment in plegmon of the hand the author had no spread of the inflammatory process in the tendon sheath to produce a secondary tenosynovitis. Because no other complications of the immobilized hand such as ankylosed joints and tendons atrophy of the bone with pain and retraction of the palmar aponeurosis were seen the author advocates this form of treatment.

ARTHUR F. CIRIELLO, M.D.

Blaisdell, P. C.: The Healing of Open Pilonidal Wound. *J. Am. M. Ass.* 1947 133 916.

The author points out the confusion existing in pilonidal surgery regarding uncontrolled schemes of primary closure involving special suture materials and patterns, different ways of obliterating dead space and eliminating infection and prodigious preoperative preparation. Statistical analyses of recurrence rates and healing time are incomplete and susceptible to differences of interpretation and emphasis.

Open pilonidal wounds usually heal in every respect like normal granulating wounds elsewhere. Occasionally they may exhibit varying degrees of delay in healing independent of whether the wound was left open from the start or broke down following primary suture. Such wounds the writer calls distressed wounds.

The distressed pilonidal wound is a unique entity with distinct characteristics. The bony surface underlying the pilonidal wound is a convex curve, which curve is continued in the soft parts between the coccyx and anus. A lesion limited to the flat area over the sacrococcygeal joint lacks special problems but extension into the intergluteal cleft has many untoward features.

The most common cause of delayed healing and recurrence is incomplete operative removal of the lesion and is unrelated to any unique characteristics of the pilonidal wound itself. Incomplete removal is far more common than is realized. The pathologic report can be helpful in warning of missing portions and the error may then sometimes be rectified in postoperative office care but this is impossible in a sutured wound.

The chief untoward characteristic of the open pilonidal wound and the next most common source of recurrence is the tendency of both granulation tissue and skin to bridge across. This leaves a readily overlooked underlying channel which becomes a permanent sinus unless prevented or destroyed.

Clinically recurrence in the open wound is permanent delayed healing. In contrast recurrences following suture are apt to occur long after apparently satisfactory healing. This is a great source of error in the comparative statistics of recurrence following open and closed methods.

Bridging is undeniably related somehow to infection yet the control of bridging in the open wound is not dependent on the control of infection. Infection would be impotent were it not for the force of contraction on the uniting tissues in the cleft. The conversion of wounds with steep sides to shallow forms for the prevention of bridging is called "saucerization" and the tendency to bridging varies inversely with the degree of saucerization obtained. Saucerization is urgently needed in the intergluteal cleft yet desirable saucerization there would involve preposterous loss of the buttock. Thus meticulous postoperative diligence is necessary.

Undermined skin edges at the ends of distressed pilonidal wounds is a cardinal indication of trouble. To prevent it gradual slopes of the longitudinal ends of the wound should always be obtained. All that is necessary is a simple linear incision at both ends.

If one is confronted by an overhanging skin edge, the wound should be explored and restored under anesthesia. Retained sinus remnants and deep bridging should be disposed of. Excessive granulation is an effect rather than a cause of delayed healing. It always accompanies a retained sinus postoperative bridging and overhanging ends and recedes as they are counteracted. Excessive granulations also occur with the rubbing together of the opposing surfaces of the wound. This can be treated by applying flamed adhesive to the raw wound surfaces.

Infection is not a problem of the open pilonidal wound but frequently causes sutured wounds to break down.

In the discussion Rosser suggested that during the early days of healing the broad open wound should be protected from bacterial contamination and any avoidable physical injury. Tucker pointed out the similarity between principles of pilonidal surgery and fistula surgery. McGinnis argued for the closed method citing the added morbidity of the open method. Blaisdell, in closing emphasized that the recurrence rate after the closed operation was 20 times that after the open method.

S. LYOTZ TITTELMAN, M.D.

Rountree, P. M.: Cross-Infection of Wounds in a Surgical Ward during a Trial of the Use of Oiled Blankets. *Med. J. Austral.* 1947 1: 427.

A previous investigation by the author (and Army tags) in 1946 revealed the large bacterial load carried by hospital blankets. The use of oiled blankets in a general surgical ward was studied in order to determine whether such blankets would have any effect on the incidence of wound cross-infection.

The blankets were collected, marked distinctively, laundered and oiled before the commencement of the trial. One hundred and eight blankets were

used this number was considered likely to be sufficient for the duration of the experiment. The blankets were washed in the hospital laundry in the usual way in three batches of 36 blankets each, and after the final rinse were oiled with a "fixanol C" oil and water emulsion. This emulsion consisted of the following components: water 60 pounds, white oil, 15 pounds, fixanol C, 6 pounds. Twenty-four pounds of this emulsion mixed with water to give a 1 in 10 dilution were used for each load of 36 blankets. The average oil content on drying was 5 per cent and the concentration of "fixanol C" was calculated to be approximately 1 in 800. The treated blankets remained in continuous use during the 4 months period of the trial. Since the number of blankets on any one bed is often altered, it was not practicable to arrange for the exclusive use of a set of blankets for each individual bed. All oiled blankets therefore came out of and were returned to the common pool as the occasion required.

At the conclusion of the trial samples were taken from unused oiled blankets stored in the linen cupboard from oiled blankets on 10 different beds in the male ward and from unoiled blankets on 10 different beds in the female ward. The unoiled blankets may or may not have been in use as long as the oiled blankets, but serve as a typical sample of the normal hospital blankets. These samples were examined for their total numbers of bacteria per gram of blanket and for the presence of hemolytic streptococci.

Swabs were taken from the wounds of all patients the day before the commencement of the trial and thereafter at intervals of 1 week during the course of the test. In a few cases, more than a week elapsed between operation and the first removal of the dressing. In such cases the wound was swabbed when the dressing was removed. The swabs were plated on blood agar and incubated aerobically. Organisms isolated were identified as completely as possible. Hemolytic streptococci were grouped but not typed. All staphylococci were examined for coagulase production and, as far as possible with the range of phages available for phage type according to the method of Wilson and Atkinson (1945).

During the trial the ward dust was examined for the presence of hemolytic streptococci and coagulase-positive staphylococci. Bacterial counts were also taken of the air in the male ward during bed making and sweeping.

Air samples taken in the male ward during bed making supplied confirmatory evidence of the value of the oiling process in reducing the bacterial load in the blankets and so indirectly in the air. A count of 134 organisms per cubic foot of air was obtained under conditions similar to those which had previously given a count of 636 however as soon as sweeping commenced in the ward the count rose to 634 organisms per cubic foot of air.

The wounds examined included all types of general surgical wounds. The majority were in such positions that they could be considered clean surgical wounds but a number of cases included such

conditions as chronic empyema sinuses, varicose ulcer third degree burns, excisions of fistula in ano, and pilonidal sinus. Such wounds were classified as "dirty" wounds.

In the cases of "clean wounds, cross-infection was considered to have occurred if the first swab, taken a week after operation, yielded a culture of micro-organisms, if a culture followed a previously unsuccessful attempt at obtaining a culture, or if another type of organism appeared in a wound already yielding bacteria.

In the case of the "dirty" wounds, the criterion of cross-infection was the appearance in the wound of another type of organism. In 3 cases, infection was apparent at the first removal of the dressing after operation and may reasonably be assumed to have occurred in the operating theater. In the remaining cases the infections are assumed to have taken place in the ward and in many of these there is convincing evidence that this is what had actually occurred.

The most frequently occurring organism was the staphylococcus, and if coagulase production is taken as a criterion of pathogenicity pathogenic staphylococci were recovered from 18 wounds in the series. There were only 3 cases of infection with group A hemolytic streptococci. In general, the other organisms isolated cannot be considered wound pathogens, but their isolation from surgical wounds can be taken as an index of the presence of conditions which permit the transference to such wounds of bacteria, including potential pathogens.

Nose and throat swabs were taken from the serving staff of the ward. Coagulase-positive staphylococci were isolated from 5 of 24 nose swabs and from 1 of 14 throat swabs. These were typed and it was found that two of the nurses were nasal carriers of the type 5b organism. The noses of these nurses were swabbed at weekly intervals in the following weeks and they were found to be persistent nasal carriers of this type. A point which seems of considerable importance in elucidating the origin of the cases of wound cross-infection with this type is the fact that these two nurses were senior nurses who were responsible for the dressing of the wounds of the patients.

The fact that 3 of the patients infected with this organism were also found to be nasal carriers may possibly indicate that the infection in these cases was autogenous. On the other hand, other infected patients did not carry the organism in their noses and it seems more likely that the nasal strains were implanted during the patients' stay in the ward. A further point which supports this presumption is the fact that all type 5b strains isolated in the ward were penicillin resistant.

The efficacy of the "fixanol" and oil treatment in reducing the bacterial load of blankets is illustrated by the bacterial counts obtained with the blankets in this investigation. In reports by the Commission on Acute Respiratory Diseases and the Commission on Air Borne Infections (1946) it is stated that oiling of blankets reduced the numbers of bac-

teria released by 90 to 95 per cent. It would appear that treatment with formalin and oil not only reduced the numbers of bacteria releasable from the blankets but also resulted in the actual destruction of a large proportion of the micro-organisms deposited on the blankets in the secretions of the patient. However it is apparent from the incidence of wound cross-infection during the trial that oiled blankets used alone and without other dust control measures had no effect on the control of cross-infection under the conditions obtaining in the ward during the investigation. This investigation has once more emphasized the complexity of the problem of cross infection of surgical wounds. The evidence available suggests that in this trial infective particles from the blankets played little part in the production of cross-infection. The role of dust infected from other sources—for example from the bed linen or directly from the skin and nasopharynx of patients—is difficult to assess. It appears that some of the nursing staff directly or indirectly may have been responsible for a proportion of the staphylococcal infections.

BENJAMIN GOLDMAN M.D.
St. Louis, Mo.

Silverthorne N: Tetanus. *J Pediat* 6 Louis, 1947

This is a study of 77 pediatric patients afflicted with tetanus during the years 1951 to 1956 and represents a summary of the clinical observations, treatment, epidemiology and prognostic indications. Most of the cases occurred during July and August and September. The majority of the patients were between the ages of 3 and 13 years of age. There were 53 males and 24 females. Some type of trauma could be related to most instances but in 15 of the 77 there was no history of cut, scratch, or puncture wound. The incubation time varied from 1 day to 1 month, and it was observed that the shorter this period was the more seriously ill the patient. Of greater significance was the length of the invasion stage; the shorter this period, the more likely the patient was to succumb. Active immunization for children is urged.

Proper treatment should consist of quiet in a darkened room with constant nursing attention. Intravenous fluids when oral feedings are contraindicated, prompt intramuscular administration of an antitoxin in doses varying from 40,000 to 300,000 units, according to the severity of the disease, penicillin when necessary for secondary infections, sedation, the author preferring seconal and cleansing of the wound, but not excision as several patients became worse following this procedure.

A general fatality rate of 47 per cent was found. For the last 10 years alone the fatality was 38 per cent. This improvement is attributed to better principles of treatment, especially the route of antitoxin administration. The author recommends that tetanus antitoxin be given intramuscularly and advises against its intravenous or intrathecal use. Evidence suggests that in recent years this disease has become considerably less severe.

españ. cir., 1946 5 141

Convulsions set in which was typical and complete in every respect for evidence of trismus. Trismus is considered a cardinal symptom of tetanus but has no satisfactory explanation.

Trismus is considered by the author as a symptom of tetanus and the author has no satisfactory explanation of the phenomenon observed in his patient. The different theories regarding the manner in which the tetanus toxin is absorbed and its mode of action are discussed at length.

STEPHEN A. ZIEGLER, M.D.

Long, A. P. and Sartwell P E: Tetanus in the United States Army in World War II Bull U S Army M Dpt 1947 7 371

United States Army Medical
Army Medical Department 1947 7 571

In the army prior to 1941 tetanus prophylaxis consisted of antitoxin administration to all men whose injuries seemed to warrant it. The major drawbacks of this measure are that (1) it may not always be possible to provide the prophylactic injection of antitoxin and (2) there is a hazard of hypersensitivity reaction.

... obtain or fluid tetanus toxoid has been ... for the prevention ...

Since 1941 plain or fluid tetanus toxoid has been used as the immunizing agent for the prevention of tetanus. This type rather than the alum precipitated tetanus was chosen because the British and French demonstrated its efficacy and safety and its sensitizing properties were less.

The administration of toxoid was based on the principle of establishing a basic immunity and reinforcing it by stimulating injections of the toxoid. All military personnel were given a basic immunization of three subcutaneous injections of 1 c.c. of tetanus toxoid at intervals of 3 weeks. Routinely at yearly intervals 1 c.c. of a toxoid stimulating dose was given, and emergency stimulating doses of 1 c.c. of toxoid were given when wounds or other injuries likely to lead to tetanus were incurred or upon manipulation of old wounds considered to be potentially contaminated by Clostridium tetani.

Studies were carried out by measuring circulating antitoxin levels after the administration of tetanus toxoid. It was shown that immediately after the initial series adequate protection existed and there was no need for prophylactic antitoxin. Additional studies were carried out to determine how long basic immunity (sufficient to allow for an adequate response to a stimulating dose) will persist. Adequate response to a booster dose of toxoid was observed for a period of at least 3 years after the basic immunization and 2 years after the routine stimulating dose. It is suggested that this protection probably con-

times for a considerably longer period. However it still would appear wise to continue the administration of emergency stimulating doses of toxoid following injury and it appears that the adequate response develops well within the usual incubation period of tetanus.

Reactions to toxoid are few and may be of two types. The first nonspecific in nature may result in local soreness at the injection site, headaches, general malaise and occasionally chills and fever. The second type is characterized by the early appearance (within 30 minutes after injection) of flushing, itching of the skin, urticarial eruptions and occasionally edema of the lips, eyelids or glottis. It is believed that reactions of this type were due to hypersensitivity to a previous dose. Following discontinuance of the use of certain toxoids with peptone components reactions dropped to less than a per 100,000 injections. Initial sensitization with the materials in current use appears to be almost nonexistent.

During World War II 13 cases of tetanus occurred among Army personnel including 4 cases resulting from injuries sustained prior to entry into active service. Only 1 case of tetanus resulted from a battle injury the other cases resulted from accidents. Penetrating injuries of the extremities were the most common cause. Six of the 13 patients had received no immunization at all, 1 had had basic immunization but no emergency stimulating injection and 4 had had basic stimulation plus an emergency stimulating injection. There were 3 fatalities in this group and the incubation period in the fatal cases was slightly less than 7 days.

During World War I the Army reported 13.4 cases of tetanus per 100,000 wounds and injuries. During the period from 1920 to 1931 there were 2.4 cases per 100,000 and during World War II 0.44 case per 100,000 a drop in frequency to 1/30 that for World War I.

From a study of the incidence of tetanus in the enemy forces and among civilians injured in military operations it is evident that without the benefit of toxoid a considerable number of cases of tetanus might well have occurred in our troops. By avoiding prophylactic antitoxin a considerable number of serious serum reactions were prevented.

The average mortality rate among American civilians from 1936 to 1938 for all age groups was 0.76 per 100,000 population per year. There has been a steady decline in tetanus mortality over many years, probably as the result of better surgery and an increased use of antitoxin. In the authors' opinion it is doubtful whether toxoid is in use on a sufficiently wide scale to have any great effect on civilian mortality.

During the war the British reported 35 cases of tetanus due to battle injury among 289,649 wounded men. In addition they found 18 cases in troops who had sustained nonbattle injuries. Boyd noted that the incubation period was shorter in the actively immunized personnel who developed tetanus, and an inadequate level of circulating antitoxin in the early

stages of infection was the cause of failure of immunization in these cases.

War experience proves the efficiency of this Army procedure for the prevention of tetanus. Reliance was not placed on a continuing state of immunity following immunization but rather advantage was taken of the rapid rise in blood antitoxin levels which occurs soon after the administration of a stimulating dose.

Active immunization should be carried out in civilian practice, particularly in the cases of children and adults whose activities are such that infection with *Clostridium tetani* may be seen. Such individuals should be furnished with a record of the procedure so that physicians subsequently treating their injuries may know that the administration of toxoid, and not antitoxin, is the prophylactic treatment of choice.

The alum precipitated toxoid lends itself to use in children in combination with other antigens such as diphtheria toxoid. Fluid toxoid, because of its more rapid absorption, may be the agent of choice for the booster dose.

In the case of an ex-serviceman stating that he was in the Army for at least a year subsequent to Pearl Harbor it would be reasonably safe to administer toxoid rather than antitoxin prophylactically. Such military service would almost certainly mean he had at least received his basic tetanus immunization; hence he could be expected to respond satisfactorily to a stimulating dose of toxoid.

ROBERT R. BENTON, M.D.

Sorensen, A. I. Chronic Meningomyelitis following Intraspinal Tetanus Antitoxin Therapy for Tetanus (Contributo allo studio delle complicanze croniche post-tetaniche del tetano. *Meningomyelite cronica insorta dopo microterapia antitetanica*). *Polidiolo* sez. prat. 1937 II 38.

A patient was cured of tetanus following the administration of tetanus antitoxin by means of the intraspinal and intramuscular routes. One month later she developed a spastic paralysis, with disturbance of sensation and loss of sphincter control. Characteristic myelographic studies showed an obstruction in the ninth dorsal vertebra.

A laminectomy was performed from the 4th to the 7th thoracic vertebra, which revealed a plastic leptomeningitis, attached tenaciously to the spinal cord. This produced a transitory amelioration of the symptoms, which recurred when a second laminectomy was done on the last thoracic and the first lumbar vertebrae. Vascularized chronic adhesions were found. The patient's condition became worse a high fever was present, and finally death occurred, approximately 3½ months following the onset of the condition.

The author concludes that the chronic meningomyelitis was due either to the tetanus toxin or to an antiphylactic reaction to the tetanus antitoxin.

ARTHUR F. CROSSLAND, M.D.

ANESTHESIA

Hellijas, C. S., Tovell R. M. and Holt, K. R.: Analgesia and Anesthesia in Obstetrics. *Anesthesiology* 1947 8 113.

The application with the greatest safety of any agent or method to the production of obstetric analgesia and anesthesia requires proper evaluation of the status of the prospective mother in the antenatal period, close co-operation of the obstetrician and anesthesiologist and a degree of flexibility of plan of action which will permit alterations of procedure when required.

The opiates have, to a great extent, been replaced by less depressant drugs, the most popular of which are demerol and selected derivatives of barbituric acid. Scopolamine has been the agent recently employed. Most of the combinations administered by the rectal route are still extensively employed. Mixtures of ether and oil or other paralytic and oil in conjunction with pentobarbital sodium have been advocated as has a combination of paralytic and hexyl alcohol. The barbiturate series has received a modest trial by the rectal route either as the sole agent or as an addition to rectal anesthetic mixtures. Nembutal and secobarbital dispensed in capsules act promptly following administration in this manner.

The efficacy of cyclopropane has been demonstrated. It has steadily replaced the more common anesthetics given by inhalation. Local regional and spinal anesthetics are advocated by a relatively small number of proponents. The employment of continuous caudal analgesia has served to demonstrate its usefulness in selected cases. The failure of its general applicability to obstetric practice has become evident.

At the present time at the Hartford Hospital, Hartford, Connecticut, amnesia and analgesia are most often produced by the use of a combination of nembutal, secobarbital, or sodium amylal with scopolamine. The combination of demerol and scopolamine has proved as satisfactory as the barbiturate-scopolamine medication. Continuous caudal analgesia for relief of pain during labor and for eventual delivery was employed in relatively few cases.

Since 1936 the most prominent developments have been the marked increase in employment of cyclopropane for obstetric purposes and the growing popularity of spinal anesthesia for the performance of cesarean sections. In 1945 83 per cent of cesarean sections were performed with spinal anesthesia as the basic method of choice and cyclopropane was used as the sole agent in more than 95 per cent of the cases in which an inhalation anesthetic was administered.

The increased employment of the agents for amnesia, analgesia, and anesthesia now in active use in this hospital has contributed in a most creditable manner to a decrease in fetal mortality and maternal morbidity. Two other factors must be presented to realize a true perspective of the overall decrease in

fetal and maternal mortality. These are the greater incidences of cesarean sections and forceps deliveries. MARY FRANCES POPE, M.D.

Green, H. N., Harbord, R. P., and Others: Discussion: Shock with Special Reference to Anesthesia. *Proc. R. Soc. Med., Lond.*, 1947 40 167.

In the present discussion Green stated that between general anesthesia and shock there are superficial resemblances. Observation of the anesthetic states seen in advanced adenosine triphosphate shock led the author to consider a possible relationship between the two states. Though it is not known in what way anesthesia and shock are precisely related, the view that they are supplementary rather than complementary states seems plausible.

It does not follow that, because the shocked individual requires less anesthetic, anesthesia necessarily predisposes to shock and in fact it would seem that the reverse hypothesis has more in its favor. It must be concluded that afferent nerve impulses do play some part in the complicated genesis of shock and therefore that local and regional anesthesia have some place in shock prophylaxis. Every manifestation of shock has as its outcome the conservation of body energy and fluid. Provided that the secondary toxic effects are avoided it may well be that anesthesia may actually be beneficial in reinforcing a general defense mechanism to injury. This does not mean that clinical shock is a desirable state but up to a certain point shock must be a beneficent reaction. We have no accurate measure of the safety limit.

Clinical shock is the expression of large-scale tissue injury and the treatment is solely that of restoring the injured parts to normal. In the final analysis anesthesia is the most potent weapon that we have in the prophylaxis of shock for with it damaged tissue can be removed or restored which would otherwise remain to kill.

The anesthesiologist ought to become the recognized expert in clinical shock. He has the best facilities for assessing the degree of shock and he is most directly concerned with the degree of tissue oxidation.

Harbord stated that the present confusion of thought regarding the best anesthetic for shock is because of the lumping together of various illnesses under the term "shock." This paper is based on a study of the responses of a standard type of patient under similar conditions, and covers a part of the material collected by No. 1 Traumatic Shock Research Team during the war.

In limb injuries the illness of the patient depends mainly upon hemorrhage. The signs found at operation depended upon the amount of damaged tissue dependent upon the amount of damaged tissue remaining adherent to the body. In belly injuries the same was true but to a lesser extent. Other factors caused an alteration in the signs at operation. Pressor and depressor responses were observed in both limb and belly cases.

The evidence shows that there is often a pressor effect at operation which is due to the anesthetic.

It was most probably due to a change in the carbon dioxide stimulus. The significance is that a false interpretation is obtained concerning the state of the patient: the pressor effect may reflect an additional circulatory strain and the period immediately following the removal of the mask is potentially dangerous. Other effects of anesthesia depended upon the drug employed.

With ether and cyclopropane a well marked vasodilatation occurred while with pentothal anesthesia little alteration was observed. Since it is a change imposed upon the patient by anesthesia, it may in fact be an adverse effect. It was found that the doses of anesthetic drugs in these patients were what would have been expected in normal patients undergoing similar operations. It appeared that the skill in administration was more important than the choice of anesthetic when comparisons were made between pentothal ether or cyclopropane.

MARY FRANCES FOX, M.D.

Wikle, H. T. and Ryan, R. J. Convulsions Occurring under Anesthesia. Analysis of 6 Cases. *Am J Surg* 94:7 73-83.

Convulsions during anesthesia are rather uncommon but it is important for physicians to be on the alert to treat these convulsions, and to prevent their

occurrence if possible. Convulsions during anesthesia were encountered 6 times in one year during which 2,143 anesthetics were administered on the surgical service of the Cumberland Hospital, Brooklyn, New York.

The etiology is extremely vague. The literature is replete with reports of possible causes, many of which contradict each other thereby making the situation more confusing.

Despite lack of knowledge concerning the operative factors, strict attention should be given to the preoperative care of patients, particularly those who are acutely ill and toxic. In an effort to lessen the number of convulsions during anesthesia. The reported incidence of convulsions associated with spinal anesthesia is negligible compared to that with inhalation anesthetics. It is worth while to consider the use of spinal anesthesia in these toxic patients.

The authors recommend the prompt use of sodium pentothal as advocated by Landy. Heretofore, the mortality in patients having convulsions during anesthesia was extremely high. With sodium pentothal at hand, this figure should be lower. There was only one death among the six patients herein presented and this was attributable not to the convulsion but to hepatorenal failure on the fifth postoperative day.

MARY FRANCES FOX, M.D.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Hunt, H B : Cancer of the Eyelid Treated by Radiation; with Consideration of Irradiation Cataract. *Am J Roentg* 1947 57 160.

The author presents a survey of cancer of the eyelid based on 100 cases selected from a group of 134 cases. The distribution of cancer of the eyelid according to sex shows a somewhat higher incidence in men—66 men to 34 women. Cancer of the eyelid usually begins first as a small nodular thickening or elevation located directly adjacent to the lid margin. The lesion enlarges and extends very slowly as a rule.

The cancer lesion shows a predilection for the medial portion of the lower lid and the area about the inner canthus, about four-fifths of the lesions occur in this combined area. In the present series, 48 per cent of the lesions occurred along the lower lid and 34 per cent about the inner canthus with only 6 per cent along the upper lid and 12 per cent adjacent to the outer canthus.

Carcinoma of the eyelid extends primarily by direct infiltration. Basal cell carcinoma may extend subcutaneously or may permeate locally along adjacent lymphatics. Advancing carcinoma of the eyelid may travel through the lymphatics, penetrate the orbital fascia, and give rise to intraorbital metastases. Lesions about the inner canthus tend to invade the lacrimal duct. Inner canthal lesions may spread across the base of the nose to the opposite inner canthus. Squamous cell carcinoma of the eyelid, although not common is a more serious lesion, shows greater local invasion and frequently metastasizes to the parotid or submaxillary glands.

The problem of postirradiation cataract is of paramount importance to the radiologist in the treatment of carcinoma of the eyelid by roentgen rays or radium.

The author has found an eyeshield, developed by Wölfflin to be satisfactory. It is composed of lead, 1/2 mm. in thickness and is plated with nickel for absorption of the characteristic radiation of the lead. This shield, however is not satisfactory for gamma irradiation.

The treatment applied in this series of 100 cases varied in type and combination according to the individual problem, and according to our maturity of experience at the time. Roentgen therapy was employed in 92 cases, radium therapy in 11 cases, and electro-surgical procedures in 12 cases. Further analysis shows that roentgen therapy alone was employed in 80 cases, radium alone in 3 cases, radium and roentgen rays combined in 5 cases, electro-surgery and roentgen rays in 7 cases, electro-surgery and radium in 3 cases, and electro-surgery alone in 2 cases. Roentgen therapy has now become the author's radiotherapeutic method of choice due to its proved

effectiveness accuracy simplicity and restriction of exposure more closely to the diseased area. Fractionation of treatments is advantageous in lesions of over 3 or 4 mm. in thickness in roentgen therapy. Roentgen radiation energized by 70 kilovolts (peak) is used for small and superficial lesions. In lesions over 3 or 4 mm. in thickness radiation energized by 90 kilovolts (peak) is used, while lesions infiltrating the lid are treated by 130 kilovolts (peak) of radiation using a filter of 0.25 mm. of copper and 1 mm. of aluminum. Deep infiltrations of the orbit are treated by 200 kilovolts (peak) using 0.5 mm. of copper or Thorium filter. Surgical ablation of large elevated carcinomas of the eyelid prior to roentgen therapy permits more effective radiation.

Four of the 100 patients whose cases are reviewed have died from cancer of the eyelid during the past 15 years. Therapeutic failures result from (a) advanced and inaccessable disease (b) impairment of the tumor bed by prior inadequate therapy (c) in sufficient or uneven dosage (d) incomplete follow up coverage of the lesion and (e) inadequate therapy of patients. In general, superficial roentgen therapy is very effective in the eradication of cancer of the eyelid with maximal preservation of the uninvolved tissues and with minimal injury to the eye when properly protected by an eyeshield.

FRANK L. HURLEY M D

Windholz, F : Reactions of Connective Tissue after Protracted Fractionated Irradiation of Laryngeal Carcinoma. *Radiology* 1947 48 148.

The author is chiefly concerned with connective tissue reactions as they occur after protracted fractionated irradiation. The studies were made on structures of the larynx which were irradiated because of the presence of carcinoma. In the present study the microscopic findings observed in from 1 month to 10 months after protracted fractionated irradiation are described in detail and interpreted. Numerous photomicrographs are used in the text to illustrate the various points of interest. The studies show that contrary to former belief there are profound and extensive early and late changes in the connective tissue after protracted fractionated irradiation of the larynx. These changes occur in three stages.

The first stage corresponds to a homeostatic retrogressive period which coincides with fibrinous cells of mucositis and disintegration of the epithelial cells of the mucous membrane. In this stage the most important manifestations are the exudation of fibrin and partial or complete loss of nuclear staining, and the frequent modifications in the microchemical reaction of the subepithelial collagenous fibers.

The second stage is characterized by a hypoplastic regenerative activity. Connective tissue replaces the destroyed carcinoma. The fibrinoid necrosis leads

to a regenerated connective tissue with hyaline sclerotic layers throughout the area of irradiation. This is associated with diffuse atrophy of the mucosa laryngeal glands, fat tissue and even muscles. The blood vessels are often obliterated, and the remarkable thing is that veins are more profoundly affected than arteries. The inflammatory reactions of the regenerated connective tissue are greatly reduced.

A third retrogressive stage is observed in those instances in which the irradiation was too heavy or in which the individual sensitivity of the connective tissue is higher than average. In such cases the mucosa ulcerates, the newly formed connective tissue breaks down and secondary infection follows with deep necrosis of the irradiated larynx.

It is the author's contention that the advantage of the protracted fractionated irradiation as compared to the massive irradiation given in a short time, is the fact that retrogressive and regenerative processes develop under the influence of a prolonged flow of the radiant energy. It is assumed that the loose normal connective tissue is transformed into a hyaline sclerotic connective tissue with few cells and sparse blood vessels, which is more resistant to the irradiation and consequently will tolerate a larger total dose without disintegration.

This new connective tissue also influences the general nutritive condition of the larynx, mainly in the areas near the lumen. The perichondrium which has a selective radiosensitivity because of its closed blood supply system, may be particularly affected and result in perichondritis and edema.

T. LECOTTE, M.D.

Windholz, F.: Late Changes in Mucous Membrane of the Irradiated Larynx. *Radiology* 94:7 43 374.

In his second article the author deals mainly with the changes occurring in the epithelium of the larynx following protracted fractionated irradiation. The studies are based on microscopic examinations of the mucous membrane of the larynx, made in from 1 month to 10 months after irradiation for carcinoma. The average tissue dose was 5,800 roentgens, and the treatment was administered with 200 kilovolts, Thoracur filter 8 x roentgen min. and 6 by 6 centimeter size fields. Again numerous photomicrographs are used for the purpose of illustration.

The studies reveal that the primary effect of irradiation is cell destruction. Coutard observed as early as 1922 that the epithelium of the larynx is destroyed in approximately 13 to 18 days and that the mucous membrane has regenerated in 26 days after the first irradiation. In a similar manner the author found that at the time fibrinous reaction occurs, the mucous membrane is entirely destroyed. Remarkably, when regeneration of epithelium takes place, not only the squamous cell epithelium but also the normally high columnar ciliated epithelium is transformed into a fully differentiated epidermoid epithelium exhibiting various degrees of cornification. The author was able to demonstrate the same

type of metaplasia experimentally on the irradiated larynx of guinea pigs, which were given a tissue dose of 5,000 roentgens by the protracted fractionated method during a period of 4 weeks.

The structure of the regenerated epithelium varies according to the postirradiation condition of the subepithelial connective tissues. In areas in which the subepithelial connective tissue shows an advanced hyaline change with marked scar formation, the epithelium is reduced to two to three layers, and has a very atrophic appearance. It is notable that in 2 cases out of 10 in which atrophy of the epithelium coincided with an abundance of hyaline sclerotic connective tissue, the carcinoma disappeared clinically as well as microscopically. In 2 other cases with recurrence of the cancer the epithelium was very thick and resembled the picture of a precancerous state of the epithelium, and the connective tissue appeared remarkably well preserved.

It is, therefore, the author's conclusion that after the primary epithelial reaction subsides the changing generations of the metaplastic epithelium adapt the growth and differentiation properties of their structures to the postirradiation condition of the subepithelial connective tissue.

T. LECOTTE, M.D.

Cottoni, F.: Observations on the Deep Cervical Fascia in Man. Contribution to the Study of Retropharyngeal Abscess Secondary to Tuberculous Spondylitis of the First Cervical Vertebra (Osservazioni anatomico-radiologiche sulla fascia cervicale profonda dell'uomo. Contributo allo studio dell'ascesso retrofaringeo da spondilite tubercolare delle prime vertebre cervicali). *Radiol. ital.* Milano, 1947 33 49.

Cottoni reports a case of retropharyngeal abscess due to tuberculous spondylitis of the second cervical vertebra, with anatomical studies performed upon cadavers of varying ages and both sexes for the purpose of explaining why extension in the case reported should have been in the direction of the pharynx rather than toward the posterior mediastinum, a prevailing anatomical concept would suggest.

He found that the close adherence of the deep cervical fascia anteriorly to the posterior wall of the pharynx, from the base of the skull to the fourth cervical vertebra and to the body of the third cervical vertebra, along with the insertion of the long muscles of the neck, serves to obstruct the cranial diffusion of abscesses forming in connection with the anterior portions of the first 3 cervical vertebrae and the occipital condyles.

EDWIN B. FARRINGTON, M.D.

Andersen, E., Gammelgaard, A., and De Flow Licht, E.: Hypertrophy of the Pylorus in Adults. *Acta radiol.*, Stockh., 94:6 7 357.

The authors review the literature on hypertrophy of the pylorus in adults, and present 8 cases found in 16,000 individuals in whom the stomach was examined roentgenologically during the period bet. 1900

PHYSICO-CHEMICAL METHODS IN SURGERY

1934 and 1944 at the County Hospital Gjøtøfte, Denmark.

The first 2 cases of hypertrophy of the pylorus in adults were reported by Landerer in 1879 and the authors have found 167 cases reported in the literature since then 71 per cent of them males, the age of recognition ranging from 12 to 80 years. The largest group of cases (81) was reported by Kirklin and Harris of the Mayo Clinic, in 1933 65 of the patients were males. The ages ranged from 21 to over 60 years of age rather evenly distributed by decades the largest number of patients being from 41 to 50 years of age. Preoperative diagnosis was made in only 2 of 169 cases.

The symptomatology is the same as in pyloric stenosis from other causes vague in mild cases and consisting of a slight sensation of pressure in the epigastrium after meals, more pronounced in the rarer severe cases with pain and, at times, vomiting after meals. The vomiting usually relieves the pain but the patient begins to lose weight and in the worst cases cachexia, anemia, and dehydration may ensue. The onset of symptoms is slow measured in months and years with a tendency to long intermissions. Hematemesis, melena, or occult bleeding is uncommon but has been found to occur in some cases. Ewald test meal gives normal values. In thin patients a mobile plum-sized mass may be palpable to the right of the spinal column at the level of the second to third lumbar vertebra.

The pathoanatomic change consists in hypertrophy of the circular muscular coat of the pyloric region extending from the sphincter (but either not or only slightly) involving it) proximally into the antrum for 3 to 5 cm. This finding is similar to that described in infants with pyloric hypertrophy and Crymble and Walmsley believe the adult condition to be merely a delayed expression of the infantile condition. Rönström, who followed (for years) 107 cases of pyloric hypertrophy in infants roentgenologically found that some narrowing of the channel persisted long after clinical manifestations had subsided he noted that usually not until the age of 4 the slight peristalsis becomes visible across the involved area and pointed out that at any time the gastric mucosa became swollen by hyperemia, edema and inflammatory infiltrate the relatively narrow canal would be compromised and symptoms would reappear. The authors believe that a similar mechanism probably operates in adults with recurrent symptoms and the 3 cases they had opportunity to study microscopically showed increased cellular infiltration of the mucosa superimposed on hypertrophy of the musculature of the juxtapyloric canal.

On roentgen examination the normal pyloric canal is 0.8 to 1 cm long whereas in cases of hypertrophy it measures 2 to 4 or 5 cm, has a smooth funnel shaped contour widest orally is straight if only 1 to 3 cm long but if longer it is likely to be convex toward the site of the lesser curvature and tends to terminate at the base of the duodenal bulb. Under low fluoroscopic observation the narrow canal

reveals changes in width and contour retains its fold pattern in relief view and in some cases may show just inferior to its midpoint a little prominence corresponding to the cleft between the sphincter and antral musculature oftenest on the greater curvature and distinguishable from crater by the radiance with which the contrast material is evacuated.

The authors present 8 cases which fulfilled many or all of the above roentgen criteria. Six of the patients were men. The average age was 60 years, the ages ranging from 53 to 77. Six of the patients had dyspeptic symptoms for a number of years, 1 had had symptoms for only 3 months and 1 had no distress. Vomiting had occurred in 4 cases and a positive benzdine reaction was obtained in 2. Six of the patients were operated upon and the 2 others have been under observation for 5 and 9 years, respectively. At fluoroscopy variation in width of the concentrically constricted and elongated pyloric lumen was seen in each of the cases barium being propelled through the narrow channel by peristaltic like contractions, and the authors believe this variation in channel width to be the most reliable sign in differentiating adult hypertrophy of the pylorus from the rigid motionless canal encountered in cases of prepyloric cirrhous carcinoma in which barium flows through in an even stream as through a pipe. In 5 cases longitudinal rugae were visible in the narrowed portion but it was recognized that folds may persist for some time in cases of cirrhous carcinoma. Six cases showed the small barium projections referred to above but these were inconstant in a given patient at different examinations. Six cases revealed a mild grade mushroomlike defect of the bulb base and a mobile plum sized mass was palpable in those cases in which the abdominal wall was not unusually thick.

The authors are of the opinion that the differential diagnosis between adult hypertrophic stenosis and juxtapyloric chronic peptic ulcer with flat niche is aided not only by the tendency of the latter to retain barium longer than the small cleft, but also by the frequently eccentric location of the pyloric canal as it is drawn toward the lesser curvature by cicatrix in such old ulcer cases. They believe that when all these points are kept in mind it is possible to differentiate adult hypertrophic pyloric stenosis roentgenologically from other more serious conditions, in a fair percentage of cases and thus to avoid exploration unless stenotic phenomena require relief.

LILIAN DONALDSON M.D.

Pezalut, Z. M.: Radiation Sickness in Patients Undergoing Irradiation Therapy for Cancer of the Uterine Cervix. Clinical Analysis and Study of the Therapeutic Action of Psychergline (II) male da razi nelle pazienti irradiate per cancro del collo dell'utero. Analisi clinica e studio sulla azione terapeutica della psichergina. (I) (II) metilaminopropano II. *Fed. 278* Genova 1945, 41-373.

During the years from 1931 to 1942 at the gynecological and obstetrical clinic of the University of

INTERNATIONAL ABSTRACTS OF SURGERY

Pavia, 247 patients were treated radiologically for cancer of the uterine cervix. This number represents 2.52 per cent of all the patients with gynecological conditions observed during this period. Disturbances of a general character arising during the period of irradiation therapy were noted in 138 of these patients (55.86 per cent) in 105 cases (42.5 per cent) the manifestations were of a trifling character but in 33 (13.3 per cent) they were severe. The combined method, employing radium internally and roentgen radiation externally was used. The radium treatment was given by the continuous irradiation method of Régnard and Lacazeigne 4,800 mgm. hr. through the uterus and the same amount through the vagina. The roentgen treatment was given by the Coutard method, a total of 8,000 roentgens through 4 fields (2 anterior 2 posterior) at a distance of 50 cm.

In the material studied the predisposition to irradiation sickness seemed to be greater the higher the patient was on the social scale. Thus the author ascribed to the greater intelligence of this class, both as to the powers of apprehension and appreciation. The greatest incidence of the disease occurred during the fifth decade or the period of the menopause however the sickness was quite prevalent all during the period of sexual maturity and the author believes this was due to the greater effect of the endocrine activity on the neurovegetative system during this period and particularly to the disturbances in the reciprocal physiological mechanisms in the menopause added to the disturbances following the treatment itself. An odd finding was that the condition of parity did not seem to produce any predisposition to the attacks, nor did concomitant morbidity of the sexual organs have any noticeable effects, except for a seeming increase in the predisposition in the pres-

ence of both cancer of the cervix and fibroids of the uterus. As would be expected, however the tendency toward the attacks increased according to the irradiation sensitivity of the new growth, being greatest in the epithelioma basocellular type of cancer. Also the length of time during which the tumor growth had been present had an effect, which was probably linked with the greater physical deterioration of the patient in the more advanced stages of the growth. The attacks also seemed to depend upon the amount of diffusion of the cancerous condition. As one would expect, the sensitivity of the patient increased with the duration and amount of irradiation treatment. When radium alone was used, the disturbances occurred in only about a third of the cases and they were light in character but when both radium therapy and roentgen therapy were used the severity of the attacks seemed to vary almost exclusively with the roentgen dosage applied.

The general resemblance of the manifestations of irradiation sickness to a neurovegetative disturbance suggested treatment with the sympathomimetic amine pyrythene (a benzodrine derivative). Following the use of this drug 37 patients presented complete regression of the digestive tract, secretions (disturbances of the digestive tract, secretions of weakness, and depressive mental states). The insomnia and headaches were not manifestly increased, but were even increased however the latter could be controlled by sedatives, such as the barbiturates, valerian, and bromides, and the latter by reduction of the amount of the drug given. This presented no problem as the condition improved rapidly enough, as a rule, to permit prompt reduction of the dosages in 2 or 3 days.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Muller, W. H., Jr. and Harkins, H. N.: Malignant Soft Tissue Tumors of the Lower Extremities: A Radical-Conservative Technique of Wide Excision and Skin Grafting without Amputation. *Surgery* 1947 31 245

A method of treating certain malignant tumors of the lower extremities by wide excision followed by skin grafting is presented. The technique is not advocated as a substitute for amputation nor is it felt that the percentage of cures will be as high with this technique as with amputation. It may however be applicable in those cases in which amputation is refused. While the method may be used in the treatment of any type of malignancy it is believed that it can best be used for the more slowly growing fibrosarcomas, liposarcomas, and myxosarcomas. This group comprises a relatively small proportion of malignant neoplasms however they are amenable to less radical surgery because they are slow growing, infiltrate locally, and are slow to metastasize.

An incision is made about the tumor in such a manner as to include a very wide margin of skin. The incision should extend down through the subcutaneous tissue, and an even larger area of fascia should be removed. If the tumor involves the muscles these should be excised to an equally radical degree. Frozen sections from the periphery of the excision may be of value in determining the adequacy of removal. If it is found that such structures as the sciatic nerve or great vessels are involved after excision the operation is indicated. Immediately after excision the wound is covered with split skin grafts. Postoperative x-ray therapy to most of these tumors is considered of little value. Five cases have been treated by this method the elapsed time since operation being from 5 to 24 months. FRANK F. KAKTAK, M.D.

Imler, A. E., and Underwood, J. W.: Malignant Melanoma of the Negro. *South Surgery*, 1947 13 61

The present report on 6 cases of malignant melanoma brings the total number of cases reported in the literature to 49. However the authors believe that this condition is not reported as frequently as it is seen and they estimate its frequency as compared with the white race to be 1 in 3 or 4.

They present the second reported case of malignant melanoma in the negro arising in the nose, the third reported case occurring in the mouth and the first instance of a primary lesion of the rectum.

The relative scarcity of malignant melanoma in the negro is possibly best explained on the basis of a better physiological control of pigment formation. As malignant melanomas are found in equal frequency on the soles of the feet in the white and negro

races there is no basis to support the common belief that malignant melanomas in the negro are more likely to arise in areas of partial pigmentation.

The origin of malignant melanoma is still unsettled.

Malignant melanoma in the negro is similar, in histologic appearance to the lesions seen in white individuals and there is no apparent difference in the relative malignancy. The microscopic pictures of the primary and metastatic lesions are frequently dissimilar.

The amount of pigmentation present is no indication of the degree of malignancy although it is believed that considerable amounts of melanin mean a high degree of differentiation. This is of little importance since varying amounts of pigment may exist in the same tumor.

The role of trauma as an activating agent has been stressed by many authors. Malignant melanoma is one type of malignancy which in many cases has an indisputable relationship with trauma.

The authors review the literature on malignant melanomas in the negro and present 6 previously unreported cases. EDWARD R. DOKOCHETZ, M.D.

DUCTLESS GLANDS

Keating, F. R. Jr.: Hyperparathyroidism. *Am J Otolaryngol* 1947 33 116

Hyperparathyroidism is called primary when more parathyroid hormone is produced than the body requires, and is called secondary when an increased production of parathyroid hormone is a compensatory response to some other condition. Primary hyperparathyroidism may be caused by a hyperfunctioning tumor of one or more of the parathyroids or by hypertrophy and hyperplasia consisting entirely of "wucherhelle" cells and involving all the parathyroid glands.

At first recognized only when it had produced a severe and disabling disease of the skeleton namely severe fibrosa cystica generalisata, primary hyperparathyroidism is now known to occur without these extreme changes and to vary remarkably both in the kind and intensity of its manifestations. Cases may be classified according to the presence or absence of skeletal involvement. In about a third of the cases there is classical osteitis fibrosa cystica generalisata in a third there is minimal or atypical skeletal disease and in the remainder there is no discernible evidence of skeletal involvement. In 75 to 95 per cent of cases there is calcification of the kidneys or renal stones.

Cardinal criteria. Regardless of its manifestations primary hyperparathyroidism is always characterized by an increase of calcium and a reduction of phosphorus in blood serum and by increased urinary excretion of both calcium and phosphorus.

Symptomatology. Symptoms vary greatly from patient to patient, both in number and in severity. They may be enumerated as follows:

- (1) Symptoms directly related to the chemical changes in the blood and urine per se
 - (a) Urinary symptoms: polyuria and polydipsia.
 - (b) Gastrointestinal symptoms: anorexia, nausea, vomiting, abdominal pain.
 - (c) Neuromuscular symptoms: fatigue, lassitude or stupor, weakness, loss of muscle tone, muscular atony, constipation.
- (2) Symptoms resulting from involvement of the skeleton:
 - (a) With minimal bone disease: aches and pains, backache.
 - (b) With osteitis fibrosa cystica: bone tenderness, pathologic fractures, decreased stature, pigeon breast and other deformities, cysts and tumors particularly in the jaw, metacarpal bones, and ends of long bones.
 - (c) Symptoms resulting from secondary involvement of the urinary tract
 - (a) With nephrocalcinosis (calcification of the renal substance): renal insufficiency and uremia.
 - (b) With renal calculi: renal pain, renal colic, urinary obstruction and infection, pyelonephritis and uremia.

Roentgenographic findings. Abnormalities evident in roentgenograms vary from mild reduction of bone density in cases of minimal bone disease to a striking picture in osteitis fibrosa cystica generalisata. The latter is characterized by multilocular osteoporosis, a fibrocystic change in skeletal architecture, subperiosteal cysts, fractures, tumors, large cystic lesions, and cal cysts. The entire skeleton is affected, the skull and long bones usually more so than the spinal column.

Dental findings. In cases of intensive bone disease, the abnormal metamorphosis of bone occasionally produces malocclusion and prognathism. Epulis is fairly common. Teeth sometimes fall out because of resorption of the underlying bone, but the teeth themselves are unaffected by the demineralizing process, and dental caries is, if anything, reduced. Dental roentgenograms show loss of bone architecture and a characteristic ground glass osteoporosis with disappearance of the lamina dura.

Physiologic implications of primary hyperparathyroidism without bone disease. Regardless of the site of action of parathyroid hormone, it is axiomatic that excretion of calcium in urine and feces must exceed ingestion of calcium before calcium stores in the skeleton can become depleted. Other factors being equal, patients who have less severe degrees of hypercalcemia (that is, milder hyperparathyroidism) or pericarditis (that is, milder hyperparathyroidism) are therefore most likely to escape bone involvement, but other factors thus far unknown also may be involved. The very existence of

hyperparathyroidism without bone disease from the "renal theory" over the "bone theory" of action of parathyroid hormone, although proponents of the latter point that absence of clinical or roentgenographic evidence of involvement of bone does not entirely exclude it.

Differential diagnosis. Hyperparathyroidism must be differentiated from (1) other conditions depleting the serum calcium, such as hypervitaminosis D, acute osteoporosis, multiple myeloma, sarcoidosis, and metastatic malignant lesions; (2) other conditions affecting the skeleton, i.e., senile, postmenopausal and secondary osteoporosis, secondary hyperparathyroidism, rickets, osteomalacia, Paget's disease, osteogenesis imperfecta, and osteitis fibrosa cystica disseminata.

Practically speaking, the recognition of hyperparathyroidism depends on considering the possibility in (1) all patients who have cystic or demineralizing disease of bone; (2) all patients who have renal colic or who have renal insufficiency of undetermined origin; (3) patients who have polyuria and polydipsia; and (4) patients who have severe and unexplained gastrointestinal symptoms.

Secondary hyperparathyroidism. Severe chronic renal insufficiency is accompanied by parathyroid hyperplasia involving chief cells, and sometimes by hyperplasia or renal osteitis. The exact pathogenesis of these bone lesions is in doubt. A similar hyperplasia of the chief cells of the parathyroids also occurs in rickets due to vitamin D deficiency, osteomalacia, pregnancy, lactation, and other conditions accompanied by calcium deprivation.

Treatment of hyperparathyroidism. Medical treatment is dangerous, irradiation therapy ineffective. Surgical removal of a parathyroid tumor or subtotal resection of parathyroid hyperplasia is the only effective treatment for primary hyperparathyroidism. Secondary hyperparathyroidism per se is probably a compensatory phenomenon and should not be suppressed.

Gherlinzoni G: Parathyroidectomy and Recklinghausen's Disease (Parathyroidectomia morbo de Recklinghausen). *Chir org maxillo-fac*, 1945, 30:125

Two clinical cases of fibrocystic osteitis, with bone swellings, deformities, and a history of repeated fractures incident to slight trauma, were operated upon and a search was made for parathyroid hyperplasia or adenoma. In one case that of a 58 year old white male the extremities were of excessive length and in both cases the roentgenologic examination disclosed in addition to the cystic areas, a marked calcification of the long bones. The laboratory report disclosed the presence of excessive amounts in the urine and the excretion of excessive large amounts in the urine for both cases. In the second case, that of a boy of 12 years, there were no signs of the onset of puberty. At operation no adenoma was found in either case, however normal parathyroid glands and thymus which appeared to represent normal parathyroid glands were removed from the left side.

the man after exposure of the left border of the thyroid gland. From the boy both right and left inferior parathyroids were removed.

Following the operation in the man the histologic examination showed that the tissues removed were not parathyroid, although there was a noticeable fall in the blood calcium and phosphorus. Roentgenologic examination showed that the distribution of calcium in the bones remained about the same, and 2 years later the patient suffered a fracture of the lower third of the left tibia. Five years later the patient was still below that preceding the operation, the patient was generally well and able to work, and x rays showed improved bone calcification, especially in the region of the cystic involvement of the left tibia. In the boy the calcemia decreased and remained decreased for a period of nearly 2 years of observation.

A number of osteotomies were done for correction of the deformities present and the histologic examination of the wedges of bone tissue removed at these times (all at least a month following the operation) showed evidence of much formation of osteoid tissue and intense activity of the osteoblasts.

From these experiences and a study of the literature the author concludes that there is a possibility that Recklinghausen's disease may occur in the absence of parathyroid adenoma or hypertrophy that spontaneous remissions may occur but that the simple exploratory operation without removal of even normal parathyroid tissue is inefficient and that at least some normal parathyroid should be removed in this contingency. Corrective osteotomies may be undertaken shortly after these parathyroidectomies and consolidation of the resultant dehiscences will take place in normal periods of time. The author does not wish to cast any doubt on the relationship of Recklinghausen's disease to parathyroid adenoma nor to deprecate the necessity of surgical exploration of the thyroid region in these patients.

SURGICAL PATHOLOGY AND DIAGNOSIS

Deming, C. L., Hovenman, M. S., and Greene, H. S. N: Heterologous Transplantation of Carcinoma of the Urethra. *J Urol* Balt, 1947 57 319

The selective ability of cancer to survive and to grow upon heterologous transfer offers a ready means of differentiation from other growths possessing a morphological or clinical resemblance.

The authors describe the results obtained in 2 cases of heterologous transplantation of carcinoma of the human male urethra. Both male and female guinea pigs were used as alien hosts, and heterologous transfer was successfully carried out.

In the first case the cancer originated in the posterior portion of the anterior urethra, and the section used for transfer was derived from its metastatic inguinal lymph node. Ten animals were inoculated 6 male and 4 female, and a single "take" resulted

This animal, a male was sacrificed on the eighty first day following inoculation at which time the anterior chamber of the eye was two-thirds filled by tumor.

In the second case, the cancer originated in the anterior portion of the anterior urethra, and a section of the cancer from that area was transplanted. Four animals all male guinea pigs, were selected as alien hosts, and again a single "take" resulted. The animal with the successful take was sacrificed after 43 days at which time the anterior chamber was one-half filled by tumor.

Morphologically the transplants resembled the original tumor in every respect. In the case of the adenocarcinoma, both epidermoid and adenoid architecture were present in the transplant. In the second case, the epidermoid structure of the transplant reflected that found in the original tumor.

Cancers of the urethra, like other malignant growths in man, are transplantable heterologously. The subsequent history of the 2 cases in question bears out the previous suggestion that only those tumors capable of heterologous transfer are true cancers. The growth of transplant in alien hosts reflects the morphological character of the growth in the original human host.

Snyder H. E., and Culbertson J. W.: Causes of Death in Battle Casualties Reaching Hospitals. *Am J Surg*, 1947 73 184.

The authors present a statistical report on 1,450 American battle casualties occurring in the Fifth Army Hospitals, in Italy from January 1, 1944 to May 3, 1945. The number of men dying on the battlefield or on the way to a hospital was found to be

TABLE I.—DISTRIBUTION OF DEATHS STUDIED BY PRINCIPAL WOUND GROUPS

	Number of cases	Percentage of deaths studied
Intra-abdominal	408	28.1
Intracranial	907	62.5
Thoraco-abdominal	118	8.3
Intrathoracic	4	0.3
Lower extremity with bone involvement	4	0.3
Unclassified, multiple wounds	30	2.1
Combined intra-abdominal & intrathoracic	31	2.1
Lower extremity soft tissue only	17	1.2
Intracranial (I. intravertebral)	5	0.3
Cervical		
Upper extremity with bone involvement	3	0.2
Maxillofacial, with bone involvement	4	0.3
Upper extremity soft tissue only	3	0.2
Abdominal wall	20	1.4
Total		100

TABLE II.—DATA RELATIVE TO HOSPITAL AD-MISSION ANESTHESIA SURGERY AND ETIOLOGY IN THE 523 CASES* IN WHICH THE IMMEDIATE CAUSE OF DEATH WAS SHOCK

	Died on Arrival	Dying on admission	Died before anesthesia	Died during anesthesia induction	Died during primary surgery	Died Subsequent to primary surgery	Total
Etiology of shock Trauma and hemorrhage	5	25	7		10	52	84
Contamination or sepsis plus trauma and hemorrhage			26	3		62	60
Cardiorespiratory embarrassment plus trauma and hemorrhage plus contamination or sepsis			10			48	7
Cardiorespiratory embarrassment plus trauma and hemorrhage	8	7	44	3	1	60	117
Total	13	32	127	6	11	222	471

*34 % of 30 American battle casualty deaths reported by Fifth Army Hospital January 1, 1944 to May 1, 1945
†Excludes dead on arrival and dying on admission

about ten times as great as that of men who died after reaching the hospital. The cases were studied from the standpoint of principal wound groups (Table I) and the immediate cause of death. Among the cases reviewed, 733 gross autopsy reports were available for study

Shock was named as the immediate cause of death in 523 of the 1,450 cases. In addition to these cases there were 750 other cases in which shock was a contributory or associated condition. In only 17 of the 1,450 deaths was there no evidence of shock. Loss of whole blood was the most important factor in the vast majority of battle casualties in shock (Table II). Neural trauma and/or intracranial hemorrhage or clot was second on the list, and the immediate cause of death in 213 cases. Third on the list of causes of death was nephropathy. This category includes all those cases in which death was known to be due to a lower nephron nephrosis or pigment nephropathy. Included in this group are a few cases in which mismatched blood transfusion produced the lesion also included are a few cases which sulfonamides were rather definitely the etiological agent. In the vast majority of cases, however, none of these factors could be definitely named as the cause of the nephropathy. It is believed that some other factor or factors, dependent upon a severe degree of shock over a long period of time was responsible for most of the cases. Peritonitis was fourth on the list of causes of death. Clostridial myositis was fifth on the list. A reduction in mortality in cases of this disease was noted primarily by cause of more complete surgery on all wounds, the more liberal use of blood, and the advent of intravenous use of penicillin. Pneumonia, fat embolism, thrombotic embolism, and other factors were listed as causes of death. Twenty-seven patients died of fat embolism. This diagnosis was not recorded except when microscopic reports indicated large amounts of fat in the pulmonary sections, and the record indicated a clinical behavior justifying the diagnosis.

SURGERY GYNECOLOGY AND OBSTETRICS

VOLUME 8C

OCTOBER 1947

NUMBER 4

INTRACRANIAL MENINGIOMAS SURGICAL RESULTS

FRANCIS C GRANT MD F.A.C.S., Philadelphia, Pennsylvania

BETWEEN January 1, 1936 and January 1, 1947 one thousand and one brain tumors were verified in the Neurosurgical Clinics of the University and Postgraduate Hospitals of the University of Pennsylvania. Of these 149 or 14.5 per cent were meningiomas. Our interest in this group. Although a review of this series of meningiomas at this time can show little of importance with regard to the ultimate life expectancy in many cases nevertheless certain other facts of interest will appear. Furthermore this is not the record of a single operator. The majority of these patients were operated upon by the author but his associates, assistants and residents also contributed. Hence this series represents what can be done in a neurosurgical clinic every member of which is expected eventually to be sufficient to expert to remove a brain tumor.

From the Neurosurgical Services of the University and Postgraduate Hospitals of the University of Pennsylvania School of Medicine.

Fig. 1. AR female aged 45 years. Meningioma of left inferior parietal area, right 1.5 gram. Operation was performed December 2, 1945. Removal was complete. Patient turned to previous occupation. In January 1946 she was examined August 15, 1946 and January 15, 1947. Apparently she made a complete recovery.

Fig. 2. III male aged 43 years. Meningioma of left parietal area, right 1.5 gram. Operation was performed December 2, 1945. Removal was complete. Patient turned to previous occupation. In January 1946 she was examined August 15, 1946 and January 15, 1947. Apparently she made a complete recovery.

Fig. 3. AR female aged 45 years. Meningioma of left inferior parietal area, right 1.5 gram. Operation was performed December 2, 1945. Removal was complete. Patient turned to previous occupation. In January 1946 she was examined August 15, 1946 and January 15, 1947. Apparently she made a complete recovery.

Fig. 4. SM male aged 31 years. Meningioma of right frontal area, right 1.5 gram. Operation was performed January 15, 1946. Removal was complete. Patient turned to previous occupation. In January 1947 he was examined August 15, 1947 and January 15, 1948. Apparently he made a complete recovery.

SURGICAL ASPECTS

Intracranial surgery has seen much technical improvement in the past 25 years. The development of ventriculography by Dandy made correct localization of the position of the tumor possible in over 90 per cent of cases. Electrosurgical methods as introduced by Cushing (1) vastly improved hemostasis of particular importance in attacking a tumor of the type under present consideration. From Cushing's clinic came the first description of the importance of suction in intracranial procedures (4) although Frazer had already used it for 2 years in operations on the trigeminal root. As the technique for intravenous transfusions was improved the neurosurgeon rapidly appreciated its value using at first saline alone then adding blood if necessary and finally in this clinic at least and certainly in many more routine whole blood transfusion in any intracranial procedure. Neurosurgeons have learned by hard experience how to handle increased intracranial pressure and all that it

performed October 22, 1940. He reported December 13, 1941. He has had six right Jacksonian convulsions beginning in leg. He vacillates judgment for starts a job but never finishes it. He has very slight right hemiparesis and spasticity. He is put on phenobarbital. On January 15, 1942 his condition was unchanged. He has had no more seizures.

Fig. 4. SM male aged 31 years. Meningioma of right frontal area, right 1.5 gram. Operation was completed January 15, 1946. He returned to work April 1, 1946. He reported continued improvement. He was put on phenobarbital and convulsions ceased by early April. The cranial defect was repaired by cranioplasty April 15, 1946. He reported October 15, 1946. Neurological examination was negative. The convulsions did not recur. He was unemployed.

INTRACRANIAL MENINGIOMAS SURGICAL RESULTS

FRANCIS C GRANT M.D. F.A.C.S. Philadelphia Pennsylvania

BETWEEN January 1, 1936 and January 1, 1947 one thousand and one brain tumors were verified in the Neurosurgical Clinics of the University and Postgraduate Hospitals of the University of Pennsylvania. Of these 149 or 14.8 per cent were meningiomas. Our interest in this group. Although a review of this series of meningiomas at this time can show little of importance with regard to the ultimate life expectancy in many cases nevertheless certain other facts of interest will appear further here. This is not the record of a single operator. The majority of these patients were operated upon by the author but his associates and residents also contributed. Hence this series represents what can be done in a neurosurgical clinic every member of which is expected eventually to be sufficient to expert to remove a brain tumor.

SURGICAL ASPECTS

Intracranial surgery has seen much technical improvement in the past 25 years. The development of ventriculography by Dandy made correct localization of the position of the tumor possible in over 90 per cent of cases. Electrosurgical methods as introduced by Cushing (1) vastly improved hemostasis of particular importance in attacking a tumor of the type under present consideration. From Cushing's clinic came the first description of the importance of suction in intracranial procedures (4) although Irazier had already used it for 2 years in operations on the trigeminal root. As the technique for intravenous transfusions was improved the neurosurgeon rapidly appreciated its value using at first saline alone then adding blood if necessary and finally in this clinic at least and certainly in many more routine whole blood transfusion in any intracranial procedure. Neurosurgeons have learned by hard experience how to handle increased intracranial pressure and all that it

1. on the Neurosurgical Services of the University and Postgraduate Hospitals of the University of Pennsylvania School of Medicine

1. A female aged 45 years. Meningioma of left frontal area. Weight 185 grams. Operation was performed December 2, 1935. Removal was complete. Patient returned to previous occupation February 15, 1936. She was examined August 15, 1940 and March 15, 1942. Slightly but she has made a complete recovery. 2. A male aged 45 years. Meningioma of left frontal area. Weight 142 grams. Operation was performed November 6, 1941. The tumor was removed by removal of the dura and removal of the tumor. On June 1, 1944, patient was reported as being well. 3. A male aged 41 years. Meningioma of left frontal area. Weight 142 grams. Operation was performed November 6, 1941. The tumor was removed by removal of the dura and removal of the tumor. On June 1, 1944, patient was reported as being well. 4. A male aged 41 years. Meningioma of left frontal area. Weight 142 grams. Operation was performed November 6, 1941. The tumor was removed by removal of the dura and removal of the tumor. On June 1, 1944, patient was reported as being well.

performed October 22, 1940. He rejected December 13, 1944. He has had six right Jacksonian convulsions beginning in leg. He vacillates judgment poor. Starts a job but never finishes it. He has very slight right hemiparesis and is unable to work. On January 15, 1946, his condition was unchanged. He has had two more attacks of epilepsy. 5. A male aged 35 years. Meningioma of right frontal area. Weight 185 grams. Removal was complete. Operation was performed January 15, 1941. He returned to work April 1, 1941. He rejected January 15, 1941. He has had generalized convulsions every 2 to 3 weeks. He was put on phenobarbital. Convulsions continued every 2 to 3 weeks. The cranial defect was closed by cranioplasty April 5, 1944. He rejected October 15, 1944. Neurological examination was normal. The patient was unemployed.

implies before during and after operation. Ventricular tap will produce relief from intra cranial tension just prior to operation thus materially reducing bleeding from the skin flap. Any tendency of the brain to herniate after the dura is opened is diminished and the ease of tumor exposure and removal thereby increased. Wiring the bone flap silk sutures, possibly deep and always superficial rubber tissue drains in all craniotomy wounds keep the flaps flat and safe. But in this clinic tap of the lateral ventricle after intracranial surgery is the chief reliance in reducing post operative tension within the skull. A patient suspected of having an intracranial mass lesion is very rarely operated upon without air studies preferably of course a ventriculogram. Parieto-occipital burr holes for ventricular tap usually bilateral are inserted in every instance. Through these perforations ventricular tap can be done for relief of pressure preoperatively or postoperatively and ventricular estimation or ventriculography carried out. The fact that only three tumors in this series were not surgically exposed at the first operative procedure is fair evidence of the value of such studies.

Proper supportive measures during the operative period are essential. Intravenous saline has been used routinely in this clinic since 1925. Now every patient is given at least 500 cubic centimeters of blood. This transfusion is completed just before the bone flap is replaced so that any consequent rise in blood pressure will produce oozing which the operator can check before the wound is closed. But one postoperative clot requiring re-elevation of the bone flap occurred in this series fortunately with recovery. In another case a clot was found at autopsy and considered to be of sufficient size to have been a factor in the fatality. Since autopsy was performed on every case in which a fatality resulted this record can be substantiated. In but 6 cases was a two stage operation considered necessary: a bilateral frontal 350 gram meningioma in a 14 year old boy and another a 250 gram meningioma of the left occipital pole in a 31 year old woman. It is our practice to turn down rather larger flaps than is customary in other clinics (see Fig 6 d). This fact plus the

routine use of preoperative air studies, has made prompt and complete exposure of the tumor possible. In 8 cases bilateral frontal flaps were fashioned where an olfactory groove meningioma was suspected preoperatively to involve both sides of the falx.

VITAL STATISTICS

Of these 149 patients 92 were females 57 males. Four of the males and 2 of the females were negroes. The youngest patient was 7 years the oldest 76. The average age at operation was 43 plus years for the women, 43 minus years for the men. The average duration of symptoms prior to operation averaged 2½ years. If 6 patients with preliminary seizures existing for over 8 years prior to operation are excluded the preoperative period at which clinical evidence of intracranial involvement appears is just a fraction over 2 years. Injury appears to have been a factor in 14 cases, all vault tumors.

POSITION OF THE TUMOR

In his recent monograph Cushing (2) has gone into great detail in describing the exact position and point of origin of each tumor in his series. We have attempted a similar accuracy in describing the position and point of origin except in those tumors arising from the sphenoid ridge. The exact point of attachment of a tumor to the ridge or whether it arose from the pterion has been difficult to determine in most instances, even after careful examination of the preoperative x-ray films and a painstaking perusal of the always detailed operative notes. This group has simply been listed therefore as sphenoid ridge tumors. Possibly some of the meningiomas described in this series as olfactory groove tumors may have originated from the inner end of the sphenoid ridge. In operating upon meningiomas in this locality especially when the tumors are bilateral the author has always been too harassed by the technical difficulties to be very certain in every case of the exact origin of the tumor. Figure 5 gives the various locations of the tumors with the surgical results. As was to be expected the more closely the tumor lay to the carotid vessels, olfactory groove, suprasellar area, sphenoid ridge, and

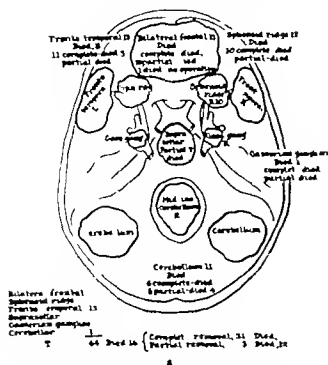

Fig. 5. Various locations of tumors with surgical results
a Tumors of base b tumors of vault

to the base of the skull gasserian ganglion and posterior fossa the higher the mortality and the less the chance of a complete removal. The surgical difficulties here are mechanical and inherent in the position of the tumor. In a second group of cases the tumor lies in the convexity of the brain and is relatively easy of access. Success or failure depends on the operator's judgment his opinion as to the patient's condition as a good or bad risk, and how much surgery is advisable.

In the first group were 64 cases with 16 deaths, a case mortality of 25 per cent in the second 82 cases with 9 deaths a case mortality of 10 per cent. In the cerebellar group of 11 cases 7 were removed 4 completely and 3

incompletely with recovery. I our died : be cause the tumor lay in the vermis of the cere bellum and was never exposed (see Fig 7 b) one, due to pontine softening following re moval of the tumor one from pneumonia in a patient who stopped breathing preoperatively and was revived by an emergency ventricular tap and the last in an elderly man shown by neurologic study to have a large tumor in volving all his cranial nerves from the fifth to the twelfth on the right. Radiologic studies showed a large defect in the bone. A chordoma was suspected but since he had intense tri geminal pain a medullary tractotomy seemed indicated. This was performed and the tumor simply verified without attempt at removal.

TABLE I — POSITION OF TUMOR IN 34 CASES WITHOUT POSTOPERATIVE SEQUELAE

Bilateral frontal	13	N PO symptoms	3 partial removal 2 4 yrs.

Atelectasis of the right lower lobe developed with death from pneumonia in 6 days. Both of the deaths in the group of suprasellar tumors were accompanied by hyperthermia. Autopsy in each case showed only partial removal of a tumor which extended backward to involve the third ventricle. In the group of 13 bilateral frontal or olfactory groove meningiomas, the cause of 1 death was inanition

and chloride deficiency on the forty second day following the removal of a 375 gram tumor in two stages, from a 14 year old boy. The second death occurred from presumed operative shock within 24 hours, following partial removal of an olfactory groove tumor from a 54 year old woman who was a good preoperative risk. The third death in a 47 year old woman in excellent physical condition was

The third death in a 47 year old woman in excellent physical condition was

Fig. 7 Autopsy specimens of 3 meningiomas in this series which were not discovered at operation. a, Tumor *en plaque* on left side of falx. Tumor not exposed because operator failed to explore close to midline. b, Midline tumor involving cerebellar vermis. Tumor believed to lie in cerebellopontine angle. Unilateral suboccipital approach failed to reveal widening of cerebellar vermis. c, Diagnosis in this case was brain abscess in right temporal lobe. Tumor found at autopsy. Relation between a tumor along sphenoidal ridge and adjacent carotid is clearly shown.

due to rupture and prompt control by clipping of the right internal carotid artery. The attack on this tumor was conducted in two stages, blood loss was never a serious factor but she developed a complete left hemiparesis never recovered consciousness and died in 48 hours. Autopsy showed no postoperative hemorrhage and no pulmonary or cardiac involvement. On 5 other occasions, in tumors unconnected with this series a clip has of necessity been applied to the right internal carotid during an operative session. Three of these patients re-

covered although the left hemiparesis and hemianopsia were unfortunately complete and permanent.

Among the 5 deaths in the frontotemporal group the first occurred in a 53 year old woman 14 days following partial removal of a tumor in the left sylvian fissure and the second from surgical shock 2 hours after removal of a 168 gram meningioma from the right sylvian area in a 52 year old woman who was an unfavorable risk. This death was due to bad surgical judgment as a one stage rather than

a two stage procedure was used. The third death occurred 6 days postoperatively from meningitis, the only case in this series from this cause. The fourth fatality took place in a 47 year old woman with uncinate fits. Fifty five grams of a meningioma, lying in the floor of the right middle fossa, were scalloped out with the bovie. Autopsy 5 days later showed

60 grams more of tumor remaining and extending down through the incisura into the right cerebellopontine angle. The fifth mortality resulted from pneumonia 5 days after the removal of an 80 gram tumor from the left middle meningeal area of a 60 year old male. He was a poor risk sent in from a neighboring asylum where because of his aphasia and

Fig 9. Typical ventriculogram. Meningioma close to falx, left cerebral hemisphere. Figure 3, frontisplane, shows this particular tumor exposed. a, Anteroposterior; b, lateral.

mental dullness a diagnosis of senile arteriosclerosis had been reached. No great technical difficulty or hemorrhage attended the removal of this tumor. The patient was semi-conscious with stertorous breathing when first seen and was considered an emergency. But he was a recent case plenty of blood was available surgical shock was never a factor and he should not have died.

The single mortality in the three gasserian ganglion tumors occurred in a patient who was operated upon as a suspected case of trigeminal neuralgia involving the second and third divisions on the left. The tumor was found and partially removed. She died of meningitis on the third day. Autopsy revealed an unsuspected right frontal abscess leaking into the ventricle.

The second group of tumors in this series is made up of those tumors lying over the convexities of the brain away from the base. There are 82 cases in this series with 9 deaths roughly a 10 per cent case mortality.

The first of these was a tumor lying in the posterior frontal area attached broadly to the falx. The patient was a good operative risk. He had a convulsion on the table and one immediately after operation. He died in 72 hours

from respiratory difficulty. Autopsy showed that he had a myxolipoma of the epiglottis which seemed sufficiently large to have been the cause for his respiratory embarrassment. Furthermore he had aplasia of his right kidney. The operative wound was clean and the tumor had been completely removed.

In the second case a 47 year old woman definitely a bad surgical risk died 10 days after a second stage removal of a 150 gram meningioma from the left frontal area. This tumor was attached to the dura over the convexity only and not to the falx. Autopsy showed a bilateral bronchopneumonia with enough old clot in the operative site to raise a definite suspicion that postoperative hemostasis had not been adequate. In the third case a 40 gram meningioma lying fully *en plaque* against the falx in the median fissure was completely overlooked following exposure of this area (see Fig 7 a). The patient died in 24 hours from increased pressure and autopsy revealed the tumor. This is 1 of the 3 cases in this series in which the tumor was not found at operation. The fourth fatality occurred in a 52 year old woman from whom 170 grams of meningioma had been removed from the right temporal area. This tumor was attached to

b

recovery, but died suddenly 2 weeks later from abrupt cardiac failure.

One of the 2 cases in the parietal group was a 39 year old woman who was a good operative risk. A 200 gram meningioma was found in the parietal area attached to the dura only. An attempt to remove this lesion at one stage resulted in an immediate death on the table from operative shock. The second death occurred in a 62 year old woman with an exostosis of the left frontoparietal area. The exostosis plus a small meningioma *en plaque* was readily removed (see Fig 8 a, b, c, d). The patient made a good postoperative recovery, but died suddenly 17 days after operation as she was dressing to go home. Autopsy showed a pulmonary embolism. The wound was clean.

Two fatalities followed removal of a meningioma in the occipital area. The first of these was a 56 year old woman with a heart murmur and a uterine myoma. An 80 gram meningioma was successfully removed from the right occipital region. She died on the seventh day from bilateral bronchopneumonia and cardiac failure. Autopsy showed that the wound was entirely clean. The second death was in a 29 year old woman 6 months pregnant and a fair operative risk. An 80 gram meningioma was removed from the body and posterior horn of the left lateral ventricle. At the end of 48 hours the patient seemed to be in

the dura alone and not to the falx. The patient was not a good operative risk and the operator used poor judgment in attempting to remove the tumor at a single sitting. The patient died 2½ hours later obviously from surgical shock. The last of these frontal fatalities occurred in a 67 year old woman who was obese, hypertensive and had evidence of cardiovascular disease. A 32 gram meningioma attached to the dura was easily removed. The patient made a good immediate postoperative

good condition but died suddenly about 60 hours after operation apparently from abrupt cardiac failure. Autopsy showed the wound clean and the tumor completely removed.

In addition to these 25 operative deaths, there were 3 other cases verified as meningioma in which no operation was performed. In one case, a 55 year old woman blind deaf and aphasic, was refused operative intervention. Autopsy showed 175 grams of tumor springing from the left sphenoid ridge and filling up the left sylvian fissure. The second case was a 64 year old woman totally blind and anomic for 3 years with evidence of marked sellar erosion and x ray evidence of have an inoperable lesion. Autopsy showed a large bilateral factory groove meningioma. The third case was a 42 year old woman who was admitted because of pain in and behind her right ear and a story of a chronic draining ear for 30 years. She was mentally dull with a right sided head ache. Lumbar puncture showed 9100 white blood cells in the spinal fluid. X ray studies showed a sclerosing and destructive process in the right mastoid together with questionable erosion of the right sphenoid ridge. Tap was made for a right temporal lobe abscess without success and a mastoidectomy revealed chronic mastoiditis. She died from increased pressure about 48 hours after mastoidectomy. Autopsy revealed a large meningioma involving the right sphenoid ridge and weighing roughly 160 grams. The right anterior and middle cerebral arteries were involved (Fig 7 c).

PATHOLOGY

Our studies on the subgrouping of these cases are incomplete. The publication of Cushing's superb monograph on the meningiomas opened up many new pathologic vistas involving this particular group of neoplasms. But although his classification has been applied in the microscopic study of these tumors since 1941 time has not permitted a complete review of the 1936-1940 cases. This review has been undertaken and will be presented in the near future. Suffice it to say here that the pathologic diagnosis of each of these cases has been made and is simply meningioma, without any attempt to classify them further.

DIAGNOSIS

In 33 of these 149 verified meningiomas, localization of the lesion was impossible on the basis of careful and painstaking neurologic studies and routine x ray examinations. It must be admitted that 11 of these patients were stuporous or unco-operative so that detailed neurologic examinations including particularly visual fields could not be made. In every case proper localization was made by ventriculography (see Fig 9 a and b). The tumor was exposed and completely or partially removed in 32 of these 33 cases. The only case in which the tumor was not exposed was in that instance where it lay in the cerebellar vermis in the posterior fossa. In a second case already mentioned the patient was suspected of having a right temporal lobe abscess, the presence of a right sphenoid ridge meningioma being revealed only at autopsy. No air studies were carried out in this case.

In the remaining 115 cases, the location of the lesion was obvious either from detailed neurologic examination including of course careful study of the visual fields, or from the flat x ray plate. Inasmuch as these tumors are known to originate from the envelopes of the brain and consequently affect its surface it is of interest that of the 70 tumors, frontal temporal and parietal which from their position might affect either the motor or sensory cortices and produce either motor or sensory focal convulsions in but 21 of these 70 cases were focal convulsions recorded. Fifty nine of these 70 cases, however showed a contralateral motor loss or pathologic reflexes indicating pyramidal tract involvement.

With regard to the other means of diagnosis and localization flat x ray films were entirely negative in 48 cases. In 81 cases flat x ray films strongly suggested the position of the lesion and in 38 of these not only was the position of the lesion correctly estimated but a positive diagnosis of meningioma was reached. In 10 instances the x ray reports (see Fig 6 a, Fig 8 d and c, Fig 10, a) were entirely misleading as to the position of the tumor. In 20 cases the presence of a mass lesion was definite on the basis of the pineal shift. In the 48 cases in which an initial study of the flat plate was reported as negative, restudy of the plate af

ter the position of the tumor was known showed suggestively positive findings in 14 Ventriculograms (see Fig 9 a and b) were performed in 61 cases with 2 missed diagnoses both because of insufficient air. In one of these instances, exploration on the basis of reasonably positive neurologic signs revealed a tumor. In the second case a repetition of the ventricular studies proved to be positive. A ventricular estimation was performed in 31 instances and in each case proved confirmatory of the position of the tumor already fairly well established by other means.

In 20 instances an encephalogram was carried out localizing the tumor accurately in 16 cases, with 4 failures. In these 4 cases, ventriculographic studies cleared up the situation.

Electroencephalography has not been used extensively in this clinic. In this series of cases, 13 electroencephalographic studies were made, with 11 positive and 2 incorrect diagnoses.

In 3 instances an arteriogram was used once under the suspicion that we were dealing with an aneurysm, and this lesion was ruled out by the arteriogram. In the second case the arteriogram was performed on the wrong side with negative results, and in the third case it was positive for the presence of a tumor.

The weight of these tumors may be of interest because it gives some clue as to their size (see Fig 6 c). Two of these tumors weighed over 300 grams, 4 over 200 grams, 14 over 150 grams, 15 over 100 grams, 26 over 50 grams, and 14 25 to 50 grams. The average weight of the 75 tumors in which it was recorded was 108 grams.

SURGICAL CONSIDERATIONS

In meningiomas owing to the very slow growth of the tumor the patient's physical condition is usually better than when the brain has been invaded by the more rapidly expanding gliomas. Inattention from continuous vomiting is less commonly seen. Consequently the impression has been formed that the meningiomas are better risks preoperatively. However in the past 5 years it has been customary to observe carefully the serum protein level in these patients. If the level is low preoperatively or postoperatively immediate efforts

are made by prompt use of amogen or blood to restore it to normal (5). Whole blood is used routinely at present in what, 10 years ago, would have been considered enormous amounts to maintain hemoglobin and blood pressure levels. In 27 of the last 93 operative sessions, the patients received 1000 cubic centimeters, or more, of whole blood, plus at least 500 cubic centimeters of normal saline, and in 7, 1500 to 2000 cubic centimeters were administered during or within 12 hours after the craniotomy. The recent suggestion (6) of prebleeding and subsequent autotransfusion has not been attempted. All our tumor cases are given 1500 to 3000 cubic centimeters of intravenous fluid in the first 24 hours postoperatively. I am not entirely convinced that all the blood given is essential. But, with the establishment of a bank in the hospital, blood is always available and these patients, unquestionably, are in better condition at the end of 48 hours postoperatively than they were 5 or 10 years ago, when less blood was used. Shock from exsanguination following removal of a meningioma is no longer seen.

All cranial tumor surgery in this clinic is carried out with patient in the horizontal position. The erect, or sitting position is used only in trigeminal root sections. Local anesthesia, plus morphine is the anesthesia of choice in craniotomy for a supratentorial tumor. An adult who is not stuporous preoperatively receives $\frac{1}{4}$ grain of morphine an hour before coming to the theater. Restlessness during operation is controlled by $\frac{1}{4}$ grain of morphine or by small amounts of sodium pentothal injected into the intravenous tube. In all suboccipital craniectomies, with patient in the prone position endotracheal ether is used. The importance of the free air way afforded by the endotracheal tube cannot be overemphasized. Venous congestion with consequent increase in intracranial pressure which even a tap of the ventricle will not relieve, is avoided. I know of no more dreadful situation that the neurosurgeon can face than to have the posterior fossa open, have something go wrong with the anesthesia, with consequent coughing and straining by the patient which may in a short 30 seconds so congest his cerebellar hemispheres that they bulge out of the wound. Any further attempt

at tumor extirpation is impossible and unless something can be done by deepening the anesthesia or repositioning the patient's head the operator may at times have trouble in closing the muscles. All this has been avoided in our experience, by skillfully administered endotracheal ether. That following the introduction of an endotracheal tube the patient has an increase in his laryngeal secretion, from irritation of the tube seems certain. And an increase of laryngeal secretion may lead to asphyxiation pneumonia, especially since damage to the vagus and glossopharyngeal nerves with vocal cord paralysis and loss of cough reflex not infrequently accompany removal of a meningioma from the posterior fossa. But the advantages of a clear air way and consequent absence of pressure during tumor extirpation far outweigh this disadvantage.

Careful hemostasis during the approach to a meningioma is of course essential. Scalp, pericranium, bone and dura, all may be highly vascular. Preoperative ventricular tap for relief of pressure will help reduce bleeding. Electrically driven drills and saws save time in turning down flaps. Speed in elevating the bone flap separating it from the tumor if the lesion has penetrated the dura, or exposing the dura and promptly coagulating its many bleeding points, saves unnecessary loss of blood. Motor driven tools have halved the time required to turn down a flap. Once the tumor is exposed and its dural attachment cut off from adjacent vessels and thoroughly coagulated the most severe, early hemorrhage is controlled. In tumors attached to the dura overlying the convexity of the brain the problem is relatively simple. Is the patient's condition sufficiently satisfactory to withstand the removal of a tumor presumably of some size? Once the cortical vascular connections to the tumor have been secured a simple matter with electrocoagulation but little bleeding usually occurs from deeper vessels. In 5 of our patients disaster followed what seemed to be the relatively bloodless removal of a convexity tumor. In every instance the tumor was large weighing between 150 and 200 grams. Cortical resection was necessary in each case to obtain sufficient room to deliver the tumor. In 3 cases the blood pressure dropped out

suddenly about 30 minutes after the tumor had been removed, after hemostasis was apparently complete and the wound ready for closure. In the other 2 cases shock appeared an hour after return to the ward. In all these instances, no amount of intravenous fluid or pressor substances were of any avail. In no case did autopsy show hemorrhage of any amount into the tumor bed. These tumors were all of sufficient size to have compressed the midbrain. Possibly a too sudden removal of the tumor with too abrupt release of midbrain pressure caused failure of sympathetic control.

When a meningioma lies along the midline the ease or difficulty of its removal depends upon the extent of its attachment to the falx whether or not the longitudinal sinus is invaded and the rolandic vein compromised. If the dura between the longitudinal sinus and the tumor can be transected much of the blood supply to the tumor is cut off. In these tumors attached to the sinus, the better method of attack is to deliver them from the brain laterally and swing them medially across the sinus. Then the extent of sinus involvement can be seen from the undersurface of the dura, and a better chance is had to shave the dura off close to the sinus without entering it. In complete removal of a tumor in this position is often unavoidable particularly if the sinus is involved behind the entrance of the rolandic vein. Injury to the sinus in this region unless it has been invaded and obstructed by the tumor will lead to disastrous neurologic sequelae. Coagulation of any tumor remnants lying against the falx close to the sinus is, of course indicated. If the sinus has been invaded and obstructed by tumor its excision plus the adjacent dural attachment of the tumor should be carried out. Recently in a large bilateral frontal tumor in this series the anterior 15 centimeters of falx with both superior and inferior longitudinal sinuses were removed with the tumor. Fortunately no motor symptoms developed since the venous return had already been obstructed.

In the removal of sphenoid ridge or olfactory groove meningiomas, the hazard is damage to the carotid artery or its branches. In right handed persons, amputation of the right

frontal lobe is always justified if thereby a better exposure can be obtained. The carotid vessels are always behind and below the tumor. The right anterior cerebral can usually be clipped without causing neurologic sequelae. Complete removal, with dural attachment of a large meningioma in this subfrontal area requires skill, courage and a certain amount of luck. A very close calculation must be made. Should the inner third of the tumor be completely removed when enough has already been extirpated to produce great relief of symptoms while further attempt may tear the carotid, with hemiparesis certain to follow its ligation?

The results of surgical attack upon a meningioma in the posterior fossa depend upon the relationship of the tumor to the vagus nerve and brain stem. Many of these tumors spring from the arachnoid fibroblasts in the porus acusticus internus and are no more difficult or dangerous to remove than an angle tumor. The vagus lies loosely along the lower pole of the tumor and can be readily separated from it. A second group arises from the edge of the posterior lacerated foramen and involve the vagus directly. Removal of such a tumor is impossible without total injury to the vagus and glossopharyngeal. If these nerves are injured with ipsilateral vocal cord paralysis and loss of the gag reflex great care is necessary to prevent aspiration pneumonia postoperatively. Tracheotomy is often necessary and feeding by stomach tube essential for long periods, to prevent disastrous pulmonary complications.

After the removal of a cerebral meningioma, should the dural defect produced by excision of the attachment of the tumor to this menbrane be repaired by a fascia lata or temporal fascia graft? If the defect lies over the motor cortex, we like to sew in a graft on the theory that irritative convulsive attacks are less likely to occur postoperatively. In other cases, a graft may or may not be introduced. In this series, in 44 instances, a large dural defect remained after removal of the tumor. The excised dura was replaced by a graft in 26 instances. One of these, a patient in whom a fascia lata graft was used died of meningitis. But if the flap is wired and the galea and skin

are carefully closed it seems to make little or no difference whether or not the dura is repaired. In the last years, fewer bone flaps have been completely sacrificed. In 84 cases, complete sacrifice of the flap seemed indicated in 18. Whenever possible, that part of the bone grossly involved by the tumor is removed with the electric burr and the remainder of the flap replaced (see Fig 6 b). Our records show 7 cases in which this was done over 5 years ago, and no evidence of recurrence is apparent. The patient is often spared an unsightly cranial defect if part of the bone flap can be replaced. In 3 instances, the flap was removed, boiled at once for 3 minutes, and reinserted. One of these reinserted flaps was lost 2 months later from infection.

RESULTS

In this group of 149 meningiomas, there were 25 operative and 3 nonoperative deaths, a total of 28 in all. Of the 121 survivors, we have, through the efforts of the tumor registry been able to check accurately on 113. Eleven are known to have died since 1935 either from a recurrence of the tumor in 7 cases or from intercurrent disease in 4 instances. Among the 103 survivors, 34 are known to be alive and well and working at their previous or similar jobs, in as good physical condition as they were prior to the removal of the tumor. The breakdown of the figures in this group is given in Table I. It will be noted that in 31 of these 34 cases, the tumor was completely removed so that this group can be considered to have been cured and restored to their previous economic condition. In 3 instances, the tumor was partially removed and, therefore it may be presumed that a recurrence with return of symptoms can be expected.

In this group of 149 meningiomas, therefore 31 or 20 per cent, can be considered to have been completely relieved of all their symptoms following total operative removal of the tumor. Sixty-eight other cases survived but are handicapped by postoperative complications. Seventeen are incapacitated by loss of vision, present in each instance prior to operation to a greater or less extent. In 4 of those cases, high choked disc was recorded

GRANT INTRACRANIAL MENINGIOMAS SURGICAL RESULTS

preoperatively although visual acuity was adequate Following the removal of the tumor in spite of the relief of the pressure there was a continuation of the visual loss. In 31 cases the postoperative complication is convulsions attacks. In 21 of these cases convulsions were present preoperatively and postoperatively in 10 they developed as a result of the operative procedure Fifteen of these are men 16 are women The women can carry on their occupations as housewives etc. in a fairly satisfactory manner but the men have always been compelled to change their job owing to their convulsive attacks. In 15 of these cases the convulsions are well controlled by phenobarbital and occur only every 4 to 6 months. In the other 11 cases the fits are more frequent coming on on the average every 2 weeks

The 20 remaining patients, 13 women and 7 men are handicapped either because of a complete or partial hemiparesis or spasticity in the contralateral extremities. Here again 13 are able to live reasonably useful lives but 7 seem to be badly incapacitated

Considering the whole group of 149 patients 163 operations were performed with 25 deaths As has been stated 7 patients were operated upon in two stages, 4 patients were operated upon twice and 3 patients three times for recurrence The overall mortality is 15.5 per cent

From January 1 1936 to December 31 1940 79 operations were performed on 71 patients, with 17 deaths, a case mortality of 24 per cent and an operative mortality of 21 per cent. From January 1 1941, to December 31 1946 84 operations were performed on 75 patients, with 8 deaths a case mortality of 10.6 per cent and an operative mortality of 9.3 per cent. To April 1 1947 7 additional meningiomas have been removed without a fatality

In the last 82 cases, 93 operations have been carried out with 8 deaths, a case mortality of 9.7 per cent and an operative mortality of 8.6 per cent

CONCLUSION

A review of 10 years experience with 149 cases of intracranial meningioma indicates that by proper methods diagnosis and localization of the tumor can be correctly made in 98 per cent of the cases. Electrosurgical aids suction and especially preoperative and postoperative supportive measures, plus prompt and adequate control of intracranial pressure have reduced the operative mortality in recent years from 21 to 8.6 per cent These tumors are benign Complete removal with dural attachment, precludes recurrence The surgeon should always keep this fact in mind His problem is total extirpation of the tumor with minimum damage to adjacent brain areas thus reducing neurologic sequelae. In spite of electrosurgery suction ventriculography blood transfusions the record here presented might well have been improved if a more conservative attack, as represented by a two stage procedure had been employed with greater frequency The temptation to indulge in "brilliant surgery and the prompt one stage cancellation of a meningioma seems at times to be overwhelming But if the score' as represented by a lowered mortality rate is to be improved this impulse must be sternly suppressed

THE RH FACTOR IN OBSTETRICS

Report of 572 Cases of Infants of Rh Negative Mothers 232 of
Whom Received Transfusions of Mother's Blood

HARRY W. MAYES M.D. F.A.C.S., Brooklyn, New York

WITH the growth of our knowledge of the Rh factor have come tentative applications in the field of obstetrics. It is supposed for instance, that hemolytic disease of the newborn or erythroblastosis has its origin in a difference of the Rh factor in mother and infant. It is thought that the red cells in the fetal blood passing through the placenta and entering the mother's blood stream set up an anti Rh agglutinin which in turn passes back to the fetal blood. Given sufficient agglutinins some form of blood dyscrasia results, before, at or soon after birth with a high mortality in the case of erythroblastosis. This theory of the causation of hemolytic disease of the newborn has not yet been proved but a greater incidence of erythroblastosis in infants of Rh negative mothers than in infants of Rh positive mothers has been proved statistically. Hence it has become usual to expect erythroblastosis when an Rh negative mother has a history of loss of infants. Two prophylactic measures have been advocated: cesarean section at 8 months and cord transfusion at birth. If and when the disease becomes manifest transfusions are the treatment of choice.

Since difference in the Rh factor in the mother's blood is assumed to be the cause of the disease, great stress has been laid on giving the child not the blood of its mother but that of an Rh negative group O donor. The contention of this paper is that blood of the mother can and should be given and two series of cases are presented of infants of Rh negative mothers delivered in a 3 year period at the Methodist Hospital in Brooklyn. In the first, mother's blood was given prophylactically at birth in the second no prophylactic transfu-

sion was given and when transfusions were indicated donor's blood was given. In the first group of 231 infants living at birth, there were 9 deaths, 7 in prematures, 2 in full term. There were no deaths from erythroblastosis. In the second group of 322 infants living at birth there were 9 deaths, 2 in prematures, and 7 full term 5 of erythroblastosis, 4 of other causes. Of the 5 infants who died of erythroblastosis 4 received transfusions, 1 none. No untoward effects from the transfusions with mother's blood were noted, and in a few cases in which additional transfusions were needed and donor's blood was used, reactions were practically nonexistent, in contrast to the cases in which donor's blood was used exclusively.

A brief discussion is included of 20 cases of erythroblastosis that occurred earlier than the 3 year period reported in 9 the father's blood was used in 1 both the mother's and father's blood.

Six cases of possible blood dyscrasia in infants of Rh positive mothers, occurring during the period studied are also briefly discussed.

BLOOD STUDY

We have been criticized for giving the blood of Rh negative mothers, to their babies, but our excellent results have encouraged us to continue. We have had cases of severe reaction following the use of Rh negative donor's blood group O supposedly compatible, and not infrequently transfusions of donor's blood causes little or no change in the blood picture. In marked contrast, with the use of mother's blood no reactions occur and the blood picture improves promptly. In order to justify our use of Rh negative mothers' blood, we made the following blood studies.

In 200 of the babies of Rh negative mothers who received prophylactic cord transfusions of

From the Department of Obstetrics of the Methodist Hospital. This study was aided by a grant from the Dr. Edwin F. Lindridge Fund for research in obstetrical pathology.

TABLE IIB—PARITY OF RH NEGATIVE MOTHERS

Year	Mother's blood or no transfusion			Donor's blood or no transfusion		
	Primip.	Multip.	Total	Primip.	Multip.	Total
1944	23	47	77	27	23	50
1945	3	43	46	24	26	50
1946	8	31	39	20	24	44
	34	78	112	71	73	144

TABLE IIA.—RH FACTOR

Year delivered	Rh factor	Mother's blood cord transfusion				Donor's blood or no transfusion			
		Erythroblastosis		Prematures		Erythroblastosis		Prematures	
		Total	Number	Died	Number	Total	Number	Died	Number
1944	154	77			11	39	9	8	5
1945	53	46	1		3	46	8		7
1946	48	39	6			20	8	5	
	17	23	3		15	7	2		

were only 12 prematures in the group since most of the prematures received cord transfusions. There were 18 cases of erythroblastosis, with 5 deaths 4 transfused with donor's blood 1 not transfused. Fourteen cesarean sections were done in the group with loss of 3 infants, one a stillbirth the other from erythroblastosis. Another case of erythroblastosis with recovery occurred in an infant delivered by cesarean section. Conditions at birth were good 305 fair 15 critical 2 stillbirth, 18. There were 151 primiparas 189 multiparas (Table II)

ERYTHROBLASTOSIS IN INFANTS GIVEN RH NEGATIVE MOTHER'S BLOOD

Of the 232 infants of Rh negative mothers who received transfusions of mother's blood 13 or 6 per cent either showed evidence of blood dyscrasia or there was a history of it (Table III). Two of the babies had more than 50 normoblasts to the 100 white cells, and 6 had more than 15. Blood counts showed that 8 had 4,500,000 or less red cells and 5 of these were under 4,000,000. It is interesting to guess what the blood count would have been had these babies not been transfused. The hemoglobin was 110 per cent or under in 9 of the babies, and in 5 it was under 100 per cent. Eight of the babies were jaundiced and in 5 the jaundice was very marked.

The 13 mothers had a total of only 20 living children out of 31 pregnancies, and every one of the 13 was a multipara. Five had had 1 previous pregnancy three, 2 three, 3 one, 4 with no living children one, 7.

Of the 10 babies who received a cord transfusion 4 received additional transfusions of

Rh negative donor's blood 2 had 1 2 had 2 additional transfusions. It was noticed that there were no reactions to these transfusions of donor's blood. In the presence of erythroblastosis 3 infants not given transfusions at birth were given large transfusions intravenously 75 to 90 cubic centimeters intravenously several hours or days after birth, and all 3 received additional transfusions of donor's blood. There were no reactions to the mother's blood even in 1 case in which the mother's blood had a high titer of anti-Rh agglutinin (Case 3 following previously reported in 1946 6). In 1946 the last year of the period studied no additional transfusions were needed in babies receiving prophylactic transfusions of mother's blood.

All of the babies were discharged on or before the 14th day. The smallest weighed 5 pounds 5 ounces and was of 36 weeks gestation. Judging from the birth weights of these 13 babies, premature induction of labor when erythroblastosis is anticipated is not justified.

From the results it seems fair to conclude that cord transfusion prevents onset of the disease, and if it develops, hastens recovery. Since the disease can be anticipated more readily in multiparas, our tendency was to give prophylactic transfusions to infants of multiparas rather than of primiparas. In 1945 and 1946 134 infants of multiparas were transfused as compared to 21 of primiparas (Table IIB).

Of the following cases, the first 2 illustrate very probable aborted erythroblastosis in the first, the mother had a bad history and blood studies indicated prognosis of the disease in the second, the baby was active and in good shape in spite of some evidence of the disease. In the third and fourth cases the babies were not given prophylactic transfusions, but when

1946	26337B	20	IV					6	63	34	40		7-	As only living child had had cord transfusion.
1946	26665A	20	IV			20		8.5	70	25			8-4	Baby had minor convulsions for 6 days. Normal at 6 weeks.

the disease developed the mother's blood was given with excellent results, in 1 case in spite of a high titer of anti Rh agglutinins.

CASE REPORTS (GROUP A)

CASE 1 Baby G 23279G This mother was a quintigravida, Rh negative with no living children and had been married 6 years. Her first pregnancy had ended in a 4 months miscarriage. In 1942 she was delivered of an 8 1/2 months baby which was not trans- fused and which died from erythroblastosis on the third day. In 1945 she had a 4 months miscarriage.

Her last child was born May 26 1946. The patient was now 32 had been pregnant 5 times, and had no living children. She came to me shortly after becoming pregnant and was given 30 minims of wheat germ oil daily 1/4 grain of protiodide of mercury twice daily and until the pregnancy had reached 5 months, 3 cubic centimeters of corpus luteum extract weekly by injection. The delivery was an easy Barton ro- tation of a right occiputposterior position and low forceps. The baby was immediately given 50 cubic centimeters of its mother's blood by cord trans- fusion. The baby was of 39 weeks gestation cried spontaneously had a good color and weighed 6 pounds 3 1/4 ounces. The mother was Rh negative the father Rh positive and the

baby Rh positive. The placental blood showed 3 800,000 red cells and the hemoglobin was 95 per cent. Following the transfusion the red cells were 4,050,000 and the hemoglobin 150 per cent. There were no normoblasts.

On the day following delivery the baby was slightly jaundiced and this increased considerably. There were also areas of ecchymoses over the body most noticeable on the extremities. In spite of the jaundice and the ecchymoses the baby seemed to be doing nicely and the red cells and the hemoglobin increased. On the second day following delivery the red cells were 5,700,000 and on the fourth 6,600,000 with a hemoglobin of 147 per cent. When the baby was 8 days old the hemoglobin was 136 per cent and the red cells 5,680,000. The baby was somewhat dehydrated on the fifth day and was given 50 cubic centimeters of saline solution by dlysis. The baby was breast fed and was discharged from the hospital on the eleventh day weighing 5 pounds 14 ounces. At the end of 6 weeks it was still breast fed and was doing nicely.

In anticipation of erythroblastosis I had had com- plete blood studies made in this case. The mother's blood was examined by Dr. Levine on four occasions before delivery and found to be Rh negative group O. Her husband was also group O but Rh positive and also Hr positive. This Dr. Levine thought con- firmed the prognosis of incompatibility of the in-

Fig. Erythroblastosis fetalis. Case 3

infant's blood. Three days before delivery Mrs. G's blood contained weak but distinct blocking antibodies and Dr. Levine thought there was a good possibility of an infant affected with erythroblastosis, but not too severely affected.

It is very hard to make a definite diagnosis of erythroblastosis in this baby. I am certain, however, it would have died from the disease had it not received a transfusion of Rh negative blood. Had the transfusion been delayed until definite symptoms of erythroblastosis developed, one transfusion would not have been enough to save the child, and if Rh negative blood from some other donor than its mother had been used there might have been incompatibility. Mother's blood is apparently always compatible and if there are anti-Rh agglutinins they do not seem to trouble the baby.

CASE 3. Baby M 30481 (Fig. 1) The mother of this baby was a secundigravida, primipara, 26 years old. The mother was Rh negative and the father Rh positive. She had had a normal baby in 1944. Her second child was delivered March 6, 1946 and was given 40 cubic centimeters of mother's blood by cord transfusion as a prophylactic procedure. The condition of the baby was good at birth. It weighed 6 pounds 9½ ounces, blood count showed 6,150,000 red cells, hemoglobin 103 per cent with 18 nucleated red cells. The following day the baby was extremely jaundiced but very active and otherwise seemed normal. It was breast fed. The red cells remained slightly over 6,000,000 until the eighth day, when they were 7,530,000, with 10 nucleated red cells. The baby was discharged on the 15th day having gained back its birth weight. If the jaundice in this case had been due to blood destruction, there should have been a decrease in the hemoglobin and red cell count. The jaundice must have been due to blocking of the bile ducts or damage to the liver from disease.

CASE 3. Baby A. 30557 This case has been previously reported in 1946 (6). The mother was thought to be Rh positive. No cord transfusion was given at birth. The baby soon became very jaundiced and seemed to be in critical condition supposedly due to an obstruction of the bile ducts. The baby was given 90 cubic centimeters of its mother's

blood, and on the following day it looked like a normal baby except for its color. The blood count was normal until the eighth day, when the red cells were 4,500,000 and the hemoglobin was 80 per cent. When the baby was 14 days old the red cells had dropped to 3,700,000 and the hemoglobin was 60 per cent. The baby was then transfused with 90 cubic centimeters of Rh negative blood from a compatible donor.

When the mother's blood was tested by Dr. Levine several days after the child's birth, it was found to be Rh negative with the high titer of 1:50. This baby was undoubtedly suffering from erythroblastosis and was cured by the use of the mother's blood which contained a high titer of anti-Rh agglutinins.

CASE 4. Baby F 24865. Mrs. F was a tertipara, secundipara, 34 years old, and Rh negative. She had had a normal baby in 1938, and in 1941 had toxemia of pregnancy was delivered at 8 months of a baby weighing only 3 pounds 10 ounces. On April 4, 1945 she was delivered of a male child weighing 6 pounds 14 ounces. The mother was thought to be Rh positive and no cord transfusion was given. Soon after birth the baby became very jaundiced, the hemoglobin was 96 per cent, red cells 3,500,000, and there were 30 normoblasts per 100 white cells. The baby was given 80 cubic centimeters of its mother's blood. There was no reaction, and the baby did well until it was 10 days old when the hemoglobin was 70 per cent, red cells 3,400,000. At this time a transfusion of 90 cubic centimeters of blood from an Rh negative donor was given, and the baby was discharged on the eleventh day weighing 8 ounces above its birth weight.

ERYTHROBLASTOSIS IN INFANTS NOT GIVEN RH NEGATIVE MOTHER'S BLOOD

There were 18 cases of erythroblastosis among the 340 infants not given transfusions of mother's blood. One died without receiving any transfusion and would probably have lived had it received a prophylactic transfusion of compatible blood (Case 10). In the re-

Fig. 2. Erythroblastosis fetalis. Case 5

the successful use of a prophylactic cord transfusion with donor's blood in the presence of possible erythroblastosis.

CASE REPORTS (GROUP B)

CASE 5. Baby E. 3 807 (Fig. 2) The mother of Baby E. was 34 years old secundigravida, Rh negative. She had 1 normal child, born in 1944. On December 25, 1945 she was delivered of a baby girl weighing 9 pounds 3 ounces. The child seemed perfectly normal at birth but 4 days later it was moderately jaundiced, the spleen was not palpable. The blood count showed 3,830,000 red cells and a hemoglobin of 98 per cent. There were no nucleated red cells. When the baby was 6 days old the red cells were 3,500,000 and the hemoglobin 76 per cent. The baby was given 90 cubic centimeters of Rh negative blood from a supposedly compatible donor. On the ninth day the baby was transfused with 80 cubic centimeters of Rh negative blood and with 65 cubic centimeters on the tenth but in spite of the 3 transfusions there was no increase in either the red cell count or the hemoglobin. The baby received 3 more transfusions and was discharged from the hospital on the 24th day. This baby received 6 transfusions for a total of 505 cubic centimeters of blood. In spite of the repeated transfusions the baby improved very little. On January 29, when the baby was 34 days old the red cells were 3,330,000 and hemoglobin 63 per cent.

CASE 6. Baby O. 30423A (Fig. 3) The history of this baby and the results are very similar to those of the preceding case. The mother was 35 years old, secundigravida, unipara, Rh negative. She had had 1 normal pregnancy. On January 6, 1946 she was delivered of a full term female infant weighing 8 pounds 2 ounces. The blood count on the day following de-

livery was 4,150,000 and the hemoglobin 100 per cent with 10 normoblasts. The spleen was enlarged, and erythroblastosis was suspected. The baby was given 60 cubic centimeters of Rh negative blood. Following the transfusion the baby became very cyanotic and stopped breathing. Respirations were re-established with some difficulty. The baby received 20 cubic centimeter transfusion on the 5th day and 45 cubic centimeters on the 7th. The 3 transfusions had little effect on the blood count, and by the time the baby was 15 days old, the red cells were 3,700,000 and the hemoglobin 60 per cent. When the baby was 25 days old the red cells were 3,860,000 and the hemoglobin 60 per cent. The baby was discharged on the 36th day. The baby had a total of 7 transfusions and 460 cubic centimeters of Rh negative blood.

There is little doubt but that the Rh negative blood used for these two babies was not compatible. If the blood had been compatible the severe reaction would not have occurred in the second case and the repeated transfusions in both cases would have been unnecessary.

CASE 7. Baby B. 37142. This child's mother was a quartigravida, unipara 23 years old and Rh negative. She had had 1 normal baby and 3 miscarriages. A normal baby was born on March 23, 1946, weighing 6 pounds 15 ounces. At birth the blood count showed 5,720,000 red cells and 111 per cent hemoglobin, with 3 normoblasts. When the baby was 6 days old the spleen was enlarged, the hemoglobin was 98 per cent and there were 15 normoblasts. It was given 75 cubic centimeters of Rh negative blood. Four days following the transfusion the normoblasts were 37 per 100 white cells. When the baby was 15 days old the normoblasts had increased to 94. The hemoglobin was 98 per cent and the red cells 4,500,000. The baby was given another transfusion of 75

MAYES RH FACTOR IN OBSTETRICS

cubic centimeters of Rh negative blood. It is interesting that the normoblasts should increase following the use of Rh negative blood. It apparently indicates an incompatibility.

CASE 8. Baby D 19266A. This mother was 36 years old, quintigravida, quadripara group B Rh negative and her husband was Rh positive. The mother had had 4 normal deliveries, but following the last in 1944 she had 2 transfusions. Her fifth child was born October 4, 1946 a male child weighing 7 pounds 11 ounces. The baby's condition was good at birth. A cord transfusion of mother's blood was attempted and failed. The baby was found to be Rh positive. On the day following delivery the red cell count was 3,500,000 and the hemoglobin 94 per cent. On October 6 the hemoglobin was 45 per cent. The baby was jaundiced liver and spleen enlarged. The baby was cubic centimeters of Rh negative blood were 3,300,000 and 35 cubic centimeters of the red cells were 3,300,000 given. On October 7 per cent and 80 cubic centimeters of Rh negative blood were given. The baby received 75 cubic centimeters on October 11 85 cubic centimeters on October 17, and on October 23 80 cubic centimeters, for a total of 355 cubic centimeters of Rh negative blood. On October 24 the red cells were 3,600,000 and the hemoglobin 85 per cent. Following the last 2 transfusions the hemoglobin dropped in both cases. The baby was discharged from the hospital on the 21st day and its condition was good. There is little doubt that the Rh negative blood in this case was incompatible. It was probably the means by which the baby's life was saved however. The red cells remained in the circulation long enough to help the baby over the difficult period. The baby's serum and the mother's cells showed no agglutination. No antibodies could be demonstrated in the mother's blood. Had the cord transfusion with moth-

er's blood been successful, there is no doubt the results would have been quite different.

CASE 9. Baby M 32000. This patient was a secundigravida 28 years old Rh negative and her husband Rh positive. The patient had been operated on for a patent ductus arteriosus and had a severe reaction following a blood transfusion of Rh positive blood. Her own and her husband's blood were examined before her delivery by Dr. Levine he found her husband Rh positive and her negative so that all of the offspring would be Rh positive. The mother was immunized as indicated by blocking antibodies. It was almost certain that the baby would be affected with erythroblastosis. The patient was delivered on March 24, 1946. The baby was given 40 cubic centimeters of Rh negative blood from a professional donor by cord transfusion. The baby was normal with a red cell count of 7,940,000 and a hemoglobin of 140 per cent.

The following case is of interest. This baby received no transfusions.

CASE 10. Baby N 31633. This is the only baby to be lost from erythroblastosis during the year 1945. The mother was 29 years old, a tertigravida, secundipara Rh negative. The father a daughter and the baby were Rh positive. The baby's condition was good at birth. It was 39 weeks gestation and weighed 6 pounds 2 ounces. It was slightly jaundiced. The spleen was palpable 17 hours after birth the red cell count was 6,110,000 and the hemoglobin 120 per cent. There were only 2 normoblasts. When the baby was 2 days old it was still jaundiced the spleen palpable and the blood count 5,040,000 and the hemoglobin 102 per cent. When the baby was 3 days old the red cells were 5,200,000 and the hemoglobin 90

per cent. There was some occult blood on the diaper. At this time the baby was seen in consultation with Dr. Weiner who diagnosed congenital hemolytic disease. He made this note: "If the hemoglobin drops to 80 per cent or below 60 cubic centimeters of fresh citrated blood 'O' Rh negative, or washed cells from an equivalent amount of mother's blood should be given." During this day the baby became much worse, the jaundice much deeper and the spleen had considerably increased in size during the last 24 hours. The baby died that night without receiving a transfusion. There is little doubt that this baby would not have died had it received an early prophylactic transfusion of compatible blood.

CEASAREAN SECTION IN RH NEGATIVE MOTHERS

In the group of 572 Rh negative mothers there were 23 cesarean sections, 9 in the group of 232 transfused with mother's blood and 14 in the 340 either nontransfused or transfused with donor's blood. In the group transfused with mother's blood there was 1 death the only case in which cesarean section was done prematurely to get a living baby the gestation was 34 weeks. There were 2 other small pretermatures 1 weighed 3 pounds 3 ounces and was of 36 weeks gestation, and the other weighed 3 pounds 12 ounces. Both survived.

In the group not given prophylactic transfusions of mother's blood there were 2 infant

deaths. In one, section was done for toxemia and the baby was stillborn. The other was of 39 weeks gestation it had 142 normoblasts and was transfused with 105 cubic centimeters of Rh negative donor's blood death occurred on the second day. This is the first case reported in Table IV. One other baby in this group developed erythroblastosis it was slightly jaundiced at birth and following 2 transfusions of Rh negative blood recovered.

There were 18 low classical cesareans and 5 low cervical. Ten were primary and 13 secondary. There were no maternal deaths. There were no maternal deaths in the entire group of Rh negative mothers.

It has been recommended if the mother has lost one or more children and is Rh negative, that a cesarean section be done at the eighth month in order to get a living child. I do not believe this is justified. If the baby is diseased you have not only a sick baby but also a premature one to deal with. As a rule the babies are in good shape at birth (see birth weights, Table III) but the disease develops rather rapidly and if no transfusions are given the baby dies about the third day. Immediate transfusion given as a prophylactic measure is far preferable to the use of cesarean section to insure a living child.

Fig. 4 Erythroblastosis fetalis, Case 21

PREMATURE BABIES AND THE RH FACTOR

In previous articles (5, 6) I have stressed the importance of using mother's blood for a cord transfusion when the baby is premature. If the mother is Rh negative and the baby is born prematurely, then we have double indication the transfusion will benefit the baby if it is premature and will protect it if there should be any tendency toward the development of erythroblastosis. There were 35 babies premature either by weight or gestation who received transfusions of mother's Rh negative blood with 7 deaths (Table IIA). Three of the babies were of 21 weeks gestation or less, 2 died from congenital anomalies, 1 following cesarean section of 34 weeks gestation mentioned and the remaining 1 weighed 3 pounds 9 ounces and lived only 1 hour.

In the group of babies not receiving cord transfusions of mother's blood there were 12 babies premature by gestation 37 weeks or under but only 5 by weight $5\frac{1}{2}$ pounds or under. Two of the babies died, 1 of 20 weeks gestation and 1 of 34 weeks which had a massive ventral hernia. The small number of cases in this group is explained by the fact that most of the prematures received cord transfusions

TRANSFUSIONS WITH FATHER'S BLOOD

It is of some interest to compare the findings of the 3 year period studied with 10 cases

that occurred between 1936 and 1942 in which father's blood was used (Table V). In 1936 nothing was known of the Rh factor nor were we giving prophylactic transfusions of mother's blood to infants other than prematures unless the mother had lost one or more babies from erythroblastosis. There is little doubt that these 10 babies were suffering from some form of blood dyscrasia. Father's blood was used because in some cases the mother was not considered a suitable donor, the father's blood was easily obtainable and the relationship might make the blood compatible. In 9 cases father's blood was used with transfusion of donor blood in 1 case in the tenth mother's blood was given by cord transfusion, one transfusion of 75 cubic centimeters of father's blood on the 2nd day and mother's in transfusions on the 5th and 9th days. The Rh factor was determined in only 2 of the 10 babies.

Of the 9 babies who received father's and donor's blood 5 had more than 50 normoblasts, 4 more than 100 and 2 more than 200. Red cells were less than 4,500,000 in 4 and 7 had a hemoglobin of less than 100 per cent. Six were jaundiced, 2 markedly. The 9 mothers had a total of 23 previous pregnancies with 14 living children. Seven were multiparas.

A total of 29 transfusions was given, 1 had a total of 5, 2 a total of 7. One baby was in the hospital for 38 days and 1 for 54 days.

MAYES RH FACTOR IN OBSTETRICS

Fig. 6 Erythroblastosis fetalis. Case 13.

white cells to 178 000 75 cubic centimeters of father's blood were given following this the red cells dropped over a million cells On the fifth day the baby was given 50 cubic centimeters of mother's blood and on the ninth day 80 cubic centimeters of mother's blood. The hemoglobin and red cells remained up and when the baby was 20 days old the red cells were 4,500,000 and the hemoglobin 94 per cent. The baby weighed 6 pounds 13 ounces and was a normal baby

In this case the father's blood did not help the baby but the 2 following transfusions from the mother who must have been Rh negative, were enough to keep the blood count at a satisfactory level

ERYTHROBLASTOSIS IN INFANTS OF RH POSITIVE MOTHERS

A comparatively small number of the babies of Rh negative mothers develop erythroblastosis of the 533 living infants of 572 Rh negative mothers delivered in a 3 year period only 31 or 5.8 per cent had erythroblastosis or some blood dyscrasia. The disease occurs even less frequently in infants of Rh positive mothers. Of the 5917 Rh positive mothers delivered in the same period only 6 of the babies had erythroblastosis or it was suspected erythroblastosis might develop (Table VI)

Two of the 6 babies had more than 15 nor-moblasts red cell count was less than 4 500 000 in 1 and hemoglobin less than 100 per cent

in 1 Two of the mothers were primiparas The 4 multiparas had had 12 previous pregnancies with 3 living children

Five of the babies were transfused with mother's blood receiving a single transfusion One received 3 transfusions of donor's blood total amount 200 cubic centimeters. This baby had the longest stay in the hospital 24 days. All recovered

LITERATURE

Many articles have been written concerning the Rh factor in obstetrics and the great majority of them stress the importance of giving the baby of an Rh negative mother transfusions of O Rh negative blood They also oppose the use of mother's breast milk. Leonard reported from the New York Hospital 55 cases of hemolytic disease with a mortality of 34 per cent 44 per cent of the babies had a nonspecific diarrhea. It is possible this might have been due to the fact that the babies were not breast fed and had difficulty in establishing proper intestinal flora. Two of the babies received transfusions of mother's blood when 5 to 7 days old no ill effects were noted and there was an increase in hemoglobin. One hundred seventy three transfusions of blood of an unknown Rh factor were given and 80 to 90 per cent of these must have been Rh positive. In 2 cases death followed

*M—mother's blood
D—donor's blood

the transfusion and may have been caused by it. Forty transfusions of Rh negative blood were given and in 1 case the transfusion was followed by cyanosis bloody nasal discharge hematuria, and death in 48 hours.

Litchfield reported 3 cases of erythroblastosis in 1945. One of the babies, which was not transfused until it was 24 hours old had 4 transfusions of Rh negative blood and 90 cubic centimeters of plasma from a compatible Rh negative donor. The baby stopped breathing following the transfusion of the plasma but was revived by artificial respiration and adrenalin. The baby died 24 hours later. The following note is made: "Despite the transfusions the infants became progressively worse. There is little doubt that transfusion reactions and factors other than the Rh prevented this infant from making a recovery." He reports that of 40 newborn infants who developed erythroblastosis, anemia or jaundice, 11 died.

Harville reported a case of erythroblastosis in which labor was terminated at the 8th month by cesarean section. Immediately following delivery the baby was given a cord transfusion of 60 cubic centimeters of Rh negative blood. The baby was given 2 more transfusions. The baby was normal in all respects. He comments as follows: "Cord transfusion hitherto neglected in these cases is an important adjuvant procedure in the management of the prematurely delivered erythroblastic infant."

Rh positive blood can be used to treat erythroblastosis, according to Danis *et al*. If the red cells are concentrated by siphoning off the majority of the plasma. He also states that we are impressed repeatedly with the results obtained with the use of father's blood. In many cases where the obstetrician had given one transfusion of father's blood before the patient came to us the results were quite remarkable.

Cold agglutinins described by Sanford and Gerstley accounted for the hemolysis following the use of Rh negative and Rh positive blood. At a temperature of 0 degrees Centigrade the cells would agglutinate, but at 20 or 30 degrees Centigrade there was no agglutination. He reports an infant recovering after 21 transfusions for a total of 2,300 cubic centimeters of blood over a period of 33 days.

If we are to judge from these reports and many others where reactions have followed the use of Rh negative blood then it would seem that Rh negative blood from a donor other than the baby's mother must frequently be incompatible and at times its use causes such a severe reaction that the baby dies.

COMMENTS

Our experience at the Methodist Hospital, Brooklyn has been quite in contrast to that of the great majority who have written about the Rh factor and its effect on the newborn. We have been led to believe that the Rh fac-

tor although important in erythroblastosis is not the exciting factor. If it were certainly many more babies of Rh negative mothers would develop the disease. Moreover if the anti Rh agglutinins in the mother's blood cause the hemolysis in the baby's blood we would be unable to give the mother's blood freely as we have done.

Most of the babies in the cases reported nursed their mothers without any untoward symptoms. No one has proved that anti Rh agglutinins in the mother's breast milk are absorbed from the infant's intestinal tract or that they are not destroyed by the intestinal ferments. The baby is apparently better off with its mother's milk, in spite of the anti Rh agglutinins it may contain.

When blood other than the mother's is used for transfusion of the infant there is a chance that the baby will be benefited. Reactions are quite common however and may be so severe that the baby will succumb during or soon after the transfusion. If the blood is incompatible there may be considerable loss in red cells and hemoglobin but in spite of this the baby is temporarily benefited. Repeated transfusions however are necessary to keep the baby alive even then red cells and hemoglobin may not be increased because of incompatibility. Crossmatching to determine compatibility is impractical since it is difficult to get sufficient blood from the baby unless blood is taken from the placenta at the time of delivery. Donor blood could be matched with that of the mother before the baby is born and if compatible could be given by cord transfusion at delivery.

SUMMARY

1 During the years 1944, 1945 and 1946 at the Methodist Hospital in Brooklyn Rh factor determinations were made in 7032 women and 142 or 14.7 per cent were found to be Rh negative.

2 In the same period 572 Rh negative mothers were delivered. Somewhat less than half 232 received transfusions of mother's blood 229 by cord at birth 3 later intravenously with the loss of no viable baby from erythroblastosis. In the group of 340 not receiving mother's blood there were 5 deaths

from erythroblastosis 4 received donor's blood 1 had no transfusion.

3 Comparison was made between the blood of 100 babies who received cord transfusions of Rh negative mother's blood and 100 babies not cord transfused with Rh negative mother's blood. The transfused babies had an average of 678,000 more red blood cells than the non-transfused babies.

4 A study of the compatibility of Rh negative mother's and baby's blood showed that in 80 cases there were only 10 in which there was any agglutination when the mother's cells and baby's serum was used. One baby transfused with incompatible mother's blood had no reaction.

5 A study of the compatibility of Rh positive mother's and baby's blood showed 6 in 46 cases in which agglutination occurred when mother's cells and baby's serum was used.

6 There were 13 cases of erythroblastosis or suspected erythroblastosis in which transfusions of mother's blood were given 10 by cord at birth 3 intravenously later. There were no reactions and no deaths. These 13 infants all had some blood dyscrasia or the mother had a history of losing babies from erythroblastosis.

7 There were 17 babies with erythroblastosis transfused with blood of Rh negative group O with the loss of 4 babies in 3 of whom there was severe reaction. In 9 of the 17 more than 1 transfusion was necessary.

8 A brief report is made of father's blood given before the 3 year period reported 9 babies received father's and donor's blood 1 both mother's and father's blood. Of the 9 3 died on or before the 3rd day 1 on the 16th day 2 died before their 2nd year leaving only 3 survivors. A total of 29 transfusions was given. The 1 infant who received mother's and father's blood had 4 transfusions, 3 of mother's blood 1 of father's with no help from the father's blood. This infant survived.

9 Results obtained from Rh negative donor's blood and father's blood were somewhat similar. More reactions occurred immediately following transfusion in infants given donor's blood but with both more transfusions were needed and more deaths occurred. Apparent incompatibility was common.

10 There were 6 cases of possible blood dyscrasia with recovery in babies of Rh positive mothers. Five were given a single transfusion of mother's blood 1 received 3 transfusions of donor's blood with a total of 200 cubic centimeters. Four of the 6 mothers were multiparas and had lost 11 babies.

ADDITION.—We have transfused 31 additional babies using mother's Rh negative blood since January 1947 there were no reactions and not one of the babies required second transfusion. One of the babies had 40 normoblasts in the cord smear. This makes total of 263 babies receiving

mother's Rh negative blood with the loss of no babies from erythroblastosis.

PATHOLOGICAL ASPECTS OF DEATH FOLLOWING MAJOR SURGERY

An Analytical Study of Postmortem Examinations of 57 Cases

FRANK H. TANNER, M.D. and GEORGE CULLEN M.D., Lincoln, Nebraska

DEATHS following major surgery have been reduced to a low level in the general hospitals of this country in the past decade (1, 2). Improved surgical technique, good preoperative and post operative care together with cautious selection of cases have all played a part in achieving the present low mortality rate following surgery. The surgeon, the internist, and the general practitioner are all directly concerned in the problem of death following major surgery. They are often called upon to evaluate the risk of surgery before operation and to anticipate the complications that may arise during surgery or in the postoperative period. It would seem logical to assume that one of the best ways for the physician to learn to make an accurate estimate of risk and learn to anticipate complications in individual cases would be to present an analysis of unselected post operative deaths in general hospital surgical services and to analyze the anatomic lesions found at autopsy in these cases. The presentation is primarily from the standpoint of pathologic anatomy but some clinical correlations have been attempted. Our plan is to present the statistical data without comment then to

discuss the data in the same order and finally to present a summary and conclusions.

MATERIAL

All hospital deaths following major surgery in 2 general hospitals during the years of 1943 to 1945 inclusive were reviewed and those in which autopsy was performed were selected for analytical study. A few cases were excluded where permission for autopsy was partially limited or where clinical data were so poorly recorded that correlation with pathologic findings was useless. Only those patients dying in the hospital during the same admission when surgery was performed are included in this study.

PRESENTATION OF DATA

The total major surgical procedures recorded by the hospitals during the study period was 5,699. In this group there was a total of 138 deaths, or a total mortality rate of 2.4 per cent. In this group of 138 deaths there were 64 autopsies or an autopsy rate of 45.6 per cent. During the same 3 year period, the average autopsy percentage for all deaths occurring in the same hospitals was 50 per cent (Table I).

TABLE I.—SUMMARY—1943-1945 INCLUSIVE

Total	57
31 males, 26 females	

A group of 57 cases in which postmortem examinations were made were selected for analytical study. These included 31 males and 26 females. The ages ranged from newborn to 89 years (Table II). The general types of operation are listed in Table III, together with the number of each. There were 19 different general classifications of surgical procedures and a total of 66 procedures on the 57 patients (since some patients had more than one procedure or more than one operation). There were 7 patients who had had more than one separate operation. Of the 57 patients operated upon the operation was classed as an emergency procedure by the authors (after review of the clinical data) in 29 of the cases.

The anesthetic agents employed were cyclopropane, 35; ether, 2; pentothal sodium, 2; spinal (procaine), 3; local, 2; pentothal sodium and cyclopropane, 5; and other combinations of those noted, 8 (Table IV).

The number of days after surgery that death occurred is listed in Table V. One can see that 44 of the 57 deaths (77%) occurred within the first 2 weeks after surgery.

Study of the clinical records reveals that there were recorded preoperative and postoperative diagnoses in all but 3 cases and that there was excellent agreement between preoperative, postoperative, and surgical pathological diagnoses, as shown in Table VI, how

ever the clinical records were found to be deficient when a search was made for a record of the clinical cause of death. No clinical cause of death was recorded in 31 cases. Of the 26 where some record of clinical cause of death was made, it agreed with the autopsy findings in 20 cases and disagreed in only 6.

The actual analysis of autopsy findings was found to be difficult to present in a way that would have any meaning. We found immediately that a simple tabulation of major anatomic lesions found at autopsy was very un-revealing and confusing. For example the heading 'peritonitis' without individual case comment meant nothing and could refer to postoperative peritonitis due to error in surgical technique, or could mean perforation of a bowel carcinoma after simple exploration and biopsy. Also, for example the heading

hemorrhage might mean surgical hemorrhage or hemorrhage because of a primary disease unrelated to surgery. Thus, while we have listed the causes of death as recorded at autopsy (Table VII) we feel that this is of little value. Therefore we tried to classify each death in a more analytical manner as due to (a) operative factors (shock hemorrhage, peritonitis evisceration anesthetic) and (b) nonoperative factors (pulmonary embolus heart disease other new disease occurring in postoperative period continuation of disease treated, diagnostic error with death from untreated disease). The division figures for each of these is given in Table VIII. These headings, while quite general, are much more revealing and meaningful from an analytical standpoint and serve to give a fair interpretation of the types of postoperative deaths based on postmortem studies.

The final item in this presentation of material and of figures deals with the incidental or other anatomic lesions found at autopsy which are not included in Table VII because they were not concerned directly with the clinical postoperative course or the death of the patient. These so called 'incidental findings' are given in Table IX.

DISCUSSION

In discussing the data presented above, the first item deserving of comment concerns the total mortality figures of 2.4 per cent for the 5 699 major surgical procedures. This is somewhat difficult to compare with other studies because of the few published statistical data.

tinal obstruction often due to malignant neoplasm and sometimes accompanied by resection of a portion of gastrointestinal tract. The resection group was the second largest group followed by combined exploratory laparotomy and biopsy.

In this phase of the discussion we feel that it is important to point out the fact that in 57 deaths, 7 had had more than one separate operation during their hospitalization. This does not include multiple procedures done at one time (such as bilateral hernia repair, cholecystectomy and appendectomy etc.) but operations done on different days. Some were part of multiple stage procedures, some elective multiple operations, and others were reoperated upon because of some difficulty arising after the first operation (not including two eviscerations). It would seem that this figure of over 12 per cent of the total postoperative deaths having more than one surgical procedure would point out a definite hazard and one which many times could be eliminated by choice.

Along the same line is the fact that 29 of the 57 (51%) were classed as emergency procedures by the authors after review of the clinical records. Using the definition that an emergency is an unforeseen circumstance that necessitates immediate action to attempt to save life, there probably is little that can be done to eliminate this hazard. However the immediate action taken doesn't always have to be surgery. Judicious use of conservative means in an effort, first to carry out the laboratory and clinical tests necessary to obtain a more definite diagnosis, and second to administer supportive therapy methods to get the patient in as good condition preoperatively as possible, will always be justified. The pathol-

ogist rarely does an autopsy on a patient who dies because an operation was too long delayed (i.e. few hours to few days) but he frequently sees the poor results from operations attempted before adequate diagnostic methods, conservative and supportive therapeutic measures have been carried out. Of necessity some situations demand immediate operation and also of necessity some surgery must be done without a definite diagnosis, but our study shows that this emergency group comprises over half of the postoperative deaths in which autopsies were done and therefore points the way to caution.

Since there were no deaths attributed primarily to anesthesia, no comments regarding anesthetic agents will be made other than those given in Table IV.

The number of days after surgery when death occurred is given in Table V. Forty-four or 77 per cent occurred within the first 2 weeks after surgery. We have no further comment to make on this fact.

The study of clinical records deserves only brief comment. Most were found quite complete except for lack of written note regarding the *clinical cause of death*. This is an important omission for the clinician has thus missed an opportunity to test his diagnostic acuity and has failed to record in the chart evidence of his interest in the case even though the outcome was unfavorable. He has not given the pathologist a preautopsy statement as to what problems he specifically is concerned with and thus perhaps makes the autopsy less revealing. This is an omission of recording that can easily be remedied to the advantage of all concerned.

In discussion of the causes of death as listed under the general headings of operative factors and nonoperative factors (Table VIII) it is striking to note the relatively few operative factors. The subheadings under this group are quite clear cut and need no detailed comment. Many were present in combination with nonoperative factors.

The various subdivisions under nonoperative factors will be considered in some detail. The first heading of *heart disease* consists of 12 cases in which the autopsy findings indicated that heart disease was the immediate or chief

cause of death or at least one of the major factors in death. More detailed information regarding these cases is given in Table X. The one thing that stands out most prominently is the occurrence of a combination of cardiac hypertrophy and rather severe coronary arteriosclerosis in 8 of the 12 cases. While a high incidence of coronary arteriosclerosis might be anticipated in this age group, it would appear that the presence of the two was a definite hazard in the group of postoperative deaths studied. In addition to the 12 cases tabulated in Table IX, there were other evidences of cardiovascular disease in several others of the entire group of 57 cases. Excluding the 12 referred to, there were 8 additional cases in which the heart was definitely hypertrophied at autopsy (450 grams or more); 7 additional cases in which coronary arteriosclerosis was grade III or more (2 with both hypertrophy and coronary sclerosis) and 9 additional cases in which there was clinical hypertension. In all there were 16 patients in addition to the 12 primary cardiac deaths that had either cardiac hypertrophy (over 450 grams), coronary sclerosis of at least grade III, clinical hypertension or some combination of the three. This makes an overall total of 27 patients or 49 per cent of those dying after major surgery who had clinical or anatomic evidence of cardiovascular disease.

The next item under nonoperative factors is that of pulmonary embolus. There were 10 cases in which pulmonary emboli were present. Five of these were uncomplicated by any other significant findings and 5 others were found in association with other factors considered definitely related to the patients' deaths. The 5 deaths due entirely to massive pulmonary embolus occurred 6, 10, 12, 13, and 17 days after surgery.

Under the heading of *other disease* occurring in the postoperative period we have listed 10 cases. Some of the disease processes were undoubtedly present before surgery, but are included in this group. Table XI lists the chief features of this interesting group of postoperative deaths. Six were pneumonias of severe type and serve to stress the fact that some pneumonias in the postoperative period do not respond to chemotherapy. In one interesting

TABLE XII—DEATHS FROM UNTREATED DISEASES DUE TO DIAGNOSTIC ERROR OR NO DIAGNOSIS MADE

Apparent Clinical Diagnosis	Pathologic Anatomy	N. of cases
Acute intestinal obstruction	Periampullar abscess—Olecs	
Acute pancreatitis	Mesenteric thrombosis	
Mesenteric thrombosis	Salmonella typhimurium	1
Perforated duodenal ulcer	Perforated esophageal ulcer	1
Obstructive jaundice	Hepatitis and cirrhosis	1
Probable strangulated hernia	Post-traumatic infection (fracture femoral vertebrae)	1
Total		7

case in which the patient died less than 24 hours after surgery, there was found such extensive pneumonia with abscesses that it was apparent that the process had been present before the operation. The case of hemorrhage from a large chronic duodenal ulcer (occurring during patient's convalescence from nephrectomy) serves as a most pointed example (as do all these nonoperative deaths) that a single history and physical examination on admission to a hospital may not be all revealing. It should never be assumed that because a patient does poorly after surgery that the cause is directly related to his operation. A fresh start and reconsideration of the case as if it were a new admission is sometimes indicated.

The group of cases listed as *continuation of the disease treated* needs very little comment. It includes that large group of palliative surgical procedures in the noncurable stage of carcinoma and those unsuccessful attempts to save life in mesenteric thrombosis, acute hemorrhagic pancreatitis, severe trauma, etc.

Finally, we have 7 cases in which it appeared from the records that preoperative and operative diagnoses were not definitely made or were in error and death was due to continuation of untreated disease, i.e., untreated because not diagnosed. In some of these cases the patients were almost in *extremis* when admitted and no opportunity for adequate study was possible; yet it appeared that surgery was justified. Some of these represent the most difficult diagnostic problems and are listed factually with no intent to criticize. Table

XII lists the apparent clinical diagnosis first and opposite this the anatomic findings as revealed by autopsy. Fortunately these cases are uncommon but the occurrence of 2 cases of perinephric abscess due to long standing renal lithiasis and pyelonephrosis presenting themselves for the first time with signs of acute intestinal obstruction shows the diagnostic difficulties offered to the clinician and surgeon.

In concluding this discussion we refer to Table IX which lists so called incidental findings, unrelated directly to the cause of death. These findings sometimes are more important to the survivors of the deceased than the other observations and in the cases of pulmonary tuberculosis may actually be of prophylactic value. It serves to stress the fact often overlooked that the purpose of the autopsy is not alone to determine the cause of death but also to record evidence of past diseases and of those diseases which might have been yet to become active had the patient lived.

SUMMARY AND CONCLUSIONS

1 The risk of death following major surgery in this community is low and apparently compares favorably with reported incidences of postoperative deaths from other institutions.

2 Autopsy percentage in postoperative deaths is nearly as high as in all hospital deaths in this community.

3 This group of postoperative deaths includes a relatively large number of so called emergency procedures and also a relatively large number of patients submitted to more than one operative procedure at a single hospitalization. These observations suggest that reasonable delay in an effort to make a more

accurate diagnosis and to allow time for general supportive therapy is justified. It would appear that multiple elective procedures at one hospital stay is an avoidable hazard.

4 There are relatively few deaths in this group due to purely operative or technical factors and none primarily due to anesthesia.

5 Most deaths in this study were due to nonoperative factors and while heart disease, pulmonary embolus, and unsuccessful removal of pathological processes by surgical methods accounts for most of these, there are some deaths due to other diseases which developed or occurred in the postoperative period or which were undiagnosed at operation and tax the diagnostic ability of surgeon and clinician. A recheck of the postoperative patient who is not doing well with the thought in mind that there may be present a disease process wholly unrelated to surgery would undoubtedly yield much information.

6 Nearly one half of the patients dying after major surgery in our study had clinical or anatomic evidence of cardiovascular disease. Except for an indication that coronary arteriosclerosis combined with cardiac hypertrophy is a hazard this study helps very little to solve the question of which cases of compensated cardiac disease, if any should avoid elective surgery.

7 One deficiency in clinical records was the lack of any recorded statement in regard to the clinical diagnosis of cause of death. The importance of this omission is discussed.

A STUDY OF SYSTOLIC BLOOD PRESSURE AND PULSE RATE IN TRAUMATIC SHOCK

JOHN D STEWART M.D. F.A.C.S PAUL A. KENNEDY M.D., and
HARRY W. HALE, Jr., M.D. Buffalo, New York

IN the conventional description of the clinical picture of traumatic shock prevalent in textbooks and medical literature the systolic blood pressure is recorded as low and the pulse rate as rapid. A value of 80 or below for systolic blood pressure is often taken as indicative of shock following trauma and the pulse rate is expected to be correspondingly elevated. In a fairly large civilian and military surgical experience the authors have come to believe that the clinical features of the state of traumatic shock are considerably less constant than is usually supposed. One or more of the characteristic clinical findings considered as having diagnostic and prognostic value may be absent in a patient whose condition in general presents unmistakable evidence of the state of traumatic shock. The conclusion is forced upon one that the essential disturbances of the condition such as reduction in cardiac output, reduction in peripheral blood flow and tissue anoxia are not always accompanied by the same signs. In fact the essence of the state of traumatic shock would seem to lie in the labile and transitory nature of the adjustments achieved by the organism and variation rather than constancy should be expected in its clinical manifestations. The point is of more than academic interest both to physiologists and clinicians. Accordingly it seemed worth while to attempt an evaluation of two of the reactions which are widely regarded as of critical interest in the diagnosis and prognosis of shock, namely the systolic blood pressure and the pulse rate. Rather complete notes on a group of severely wounded soldiers afforded suitable data for assay.

Detailed and careful personal observations had been made on several hundred seriously wounded soldiers treated as nontransportable

casualties at forward field hospitals. From these cases 204 were selected for study, all suffering from penetrating or perforating wounds from high explosive missiles and all presenting the clinical picture of actual or imminent shock. All had grave wounds of chest, abdomen, major bones and joints or combinations of these wounds. The amounts of plasma and blood given at various intervals had been recorded as well as the time between wounding and admission to field hospital, the time between admission and surgical operation and

TABLE I.—PLASMA AND BLOOD ADMINISTERED TO 204 GRAVELY WOUNDED SOLDIERS AND TIME INTERVALS

Intervals	Plasma				Blood

TABLE III.—SYSTOLIC BLOOD PRESSURE AND PULSE RATE IN 31 FATALLY WOUNDED SOLDIERS

Time	Systolic blood pressure				Pulse rate			
	No. of observations	High	Low	Average	No. of observations	High	Low	Average
At admission	31	30		63.8	18	60	48	50
Before operation	31	140		68.2	29	70	56	58
At end of operation	23	38		67.5	25	66	50	50

The average time intervals for the group were from wounding to admission to forward field hospital 5 minutes; from admission to operation 87 minutes; from beginning to end of operation 149 minutes.

the duration of operation. As noted elsewhere there is good reason to believe that the major cause of the state of shock in such fresh casualties is blood loss (1, 2). As shown in Table I the wounds were recent at the time the casualties were admitted to the field hospitals for treatment, the average interval between wounding and admission being just under 6 hours. The gravity of the wounds is attested by the amounts of plasma and blood considered necessary in preparation for and in conduct of surgical operation. The men were for the most part previously healthy young soldiers, the average age being 24.6 years and the oldest being 42.

For the entire group of 204 casualties, there were 31 deaths during the forward observation

TABLE IV.—SYSTOLIC BLOOD PRESSURE AND PULSE RATE IN 204 CASES

Time	Systolic blood pressure		Pulse rate	
	No. of observations	Average value	No. of observations	Average value
At admission	208	83.6	130	70
Before operation	290	120.4	294	123.6
At end of operation	200	110.8	290	117.9

period. If the cases are divided according to initial systolic blood pressure readings at admission to hospital, as shown in Table II, it is seen that some correlation appears to exist between degree of hypotension and prognosis. Exceptions are fairly numerous, however. The mortality rate of 15.2 per cent for the entire group indicates the severity of the wounds under consideration.

The data of Tables III and IV bear on the question of the prognostic value of changes in systolic blood pressure and pulse rate in the wounded. It is seen that the average values for systolic blood pressure are consistently lower at the three points of observation in the fatal cases as compared with the entire group, and the average values for pulse rate consistently higher. However, as systolic blood pressure rises preoperatively under restorative therapy, so does pulse rate as portrayed in Chart 1. Systolic blood pressure and pulse

TABLE V.—CORRELATION OF SYSTOLIC BLOOD PRESSURE AND PULSE RATE AT DIFFERENT INTERVALS IN THE EARLY CARE OF GRAVELY WOUNDED SOLDIERS

	Observations at admission			Observations before operation			Observations at end of operation		
	Pulse rate			Pulse rate			Pulse rate		
	0-30	31-100	Over 100	0-30	31-100	Over 100	0-30	31-100	Over 100
Admission systolic blood pressure over 100 (16 cases)									
	2	29	11			40	3	18	34
Admission systolic blood pressure 51-100 (53 cases)			33		14	73		14	61
Admission systolic blood pressure 30-50 (7 cases)						14		4	20
Admission systolic blood pressure (< 30 cases)						9		4	5

The pulse rates are for the same group as classified according to admission blood pressure, followed throughout the periods of observation.

ate both show a decline during the period of surgical operation. A rising pulse rate under treatment for shock does not appear to have prognostic significance if average values are considered. Furthermore, as systolic blood pressure rises toward the normal pulse rate becomes increasingly abnormally rapid. Accordingly the value for systolic blood pressure in a given case would seem to be a much better index of the patient's condition than pulse rate.

The values for systolic blood pressure and pulse rate as classified for the entire group studied are shown in Table V as the basis for computing correlation between these two factors. The values are taken at three points of observation namely at admission to the hospital immediately before operation and immediately after operation. If coefficients of correlation between systolic blood pressure and pulse rate are computed by the product moment method using Pearson's formula, we find that

- 1 For admission observations $r_1 = -.36$ for 140 cases
- 2 For observations before operation $r_2 = -.21$ for 194 cases.
- 3 For observations at end of operation $r_3 = -.10$ for 189 cases.

If it is recalled that a value of 1.0 for r indicates perfect correlation and that a zero value indicates total lack of correlation it is clear that no significant correlation can be discerned between systolic blood pressure and pulse rate. Furthermore, the coefficient of correlation becomes progressively lower under treatment. In order to demonstrate that this decrement in the value of r represents a significant trend and is not merely a chance finding the critical ratios between r values are determined. It is found that

$$C.R. \text{ for } r_1 - r_2 = 2.2$$

$$C.R. \text{ for } r_1 - r_3 = 1.7$$

$$C.R. \text{ for } r_2 - r_3 = 3.8$$

A critical ratio of 3.0 or above is highly significant and the above values therefore support in substantial degree the conclusion that changes in systolic blood pressure and pulse rate in this study are quite poorly correlated.

Chart 1. A study of systolic blood pressure and pulse rate in traumatic shock. A Pulse versus time after wounding in 31 fatal cases, B In 204 severely wounded cases, C Systolic blood pressure versus time after wounding in 204 severely wounded, D In 31 fatal cases.

SUMMARY

- 1 Values for systolic blood pressure and pulse rate in 204 freshly gravely wounded soldiers have been examined.
- 2 In nonfatal as well as fatal cases the systolic blood pressure under restorative therapy tended to rise toward normal whereas the pulse rate tended to rise away from normal.
- 3 Coefficients of correlation between systolic blood pressure and pulse rate are shown to be quite low both before and after restorative therapy and surgical operation.
- 4 Systolic blood pressure appeared to have more prognostic value than pulse rate though both showed more deviation from the normal in fatal cases than in the group as a whole.
- 5 Systolic blood pressure and pulse rate in traumatic shock should be considered as representing the momentary effect of varied and compounded physiological reactions. The frequency of exceptional values indicates that these two factors require caution in the evaluation of the state of traumatic shock.

INDICATIONS FOR SIMPLE MASTECTOMY

DANEY P. SLAUGHTER, M.D., and LAWRENCE W. PETERSON, M.D. Chicago, Illinois

THE operation of simple mastectomy may be performed as a therapeutic or as a prophylactic procedure. It should not be utilized as a diagnostic method. Unfortunately these distinctions are not always clear in the minds of many surgeons, and considerable surgical abuse of the female mammary gland results. Lack of understanding of breast pathology and the physical harmlessness of even major breast surgery are factors contributing to the casual sacrifice of this organ. The mortality from breast surgery is practically nil and the physiological effects of removal of one or both mammary glands are likewise negligible considering modern pediatric facilities. Nevertheless, conservation of tissue, and avoidance of unnecessary destruction would seem to be fundamental surgical principles. Applied to surgery of the mammary gland such a principle is valid in itself aside from the important psychological and financial considerations incident to removal of a breast.

Bloodgood's succinct remark that a simple mastectomy is too radical a procedure for benign lesions and inadequate for malignant tumors is correct in principle but would seem to be too dogmatic a condemnation of this operation. In view of the confusion that seems to exist about the indications for this surgical procedure, we have reviewed the cases seen in the tumor clinic of the Research and Educational and the Presbyterian Hospitals in an attempt to clarify the rationale for performing a simple mastectomy. These patients are referred to the tumor clinic from the entire state and probably represent a fair cross-section of medical practice. Seventy-one such patients have been reviewed and are the basis of this report.

ANALYSIS OF CASES

I Simple mastectomies for diagnosed breast lesions 21

From the Department of Surgery of the University of Illinois College of Medicine, and the Tumor Clinics of the Research and Educational and the Presbyterian Hospitals.

a. Carcinoma	9
(Palliative 3)	
(Poor risk 6)	
b. Precancerous lesions	5
(Previously diagnosed by biopsy)	
c. Mastodynia	2
d. Papillary cystadenoma	1
e. Recurrent, multiple cysto-sarcoma phyllodes	
f. Multiple, persistent draining sinuses	1
g. Tuberculosis of breast	
h. Liposarcoma	1
II Simple mastectomies for lump in breast. Pathology	13
a. Carcinoma	13
(6 converted to radical)	
b. Chronic cystic mastitis	16
c. Papillary cystadenoma	2
d. Solitary cyst	1
e. Fat necrosis	1
III Simple mastectomies for bleeding nipple. Pathology	14
a. Chronic cystic mastitis	1
b. Intraductal papilloma	3
c. Carcinoma	1
IV Simple mastectomies for eczema of nipple. Pathology	2
a. Eczema	1
b. Paget's disease	1
V Simple mastectomies for clear discharge from nipple. Pathology	1
Chronic cystic mastitis	

Group I. Twenty-one patients of this group had simple mastectomies performed after a diagnosis had been established either by biopsy or clinical recognition of an obvious lesion.

a. Nine operations were done because of cancer 3 of which were deliberately palliative for lesions considered incurable. These were large ulcerated and fungating masses. The other 6 patients with cancer were such poor surgical risks due to age or cardiovascular disease or both that a radical mastectomy was deemed inadvisable. Aside from the increased surgical risk there is no point in trying for a five year cure in an elderly patient whose physical condition can only give a reasonable life expectancy of 2 to 3 years. This, of course

requires careful evaluation as one must not err on the side of conservatism in treating cancer.

b Five of the patients in group I had a simple mastectomy performed because of a previous biopsy diagnosis demonstrating a lesion considered to be 'pre-cancerous.' It is significant that in the total series of 71 cases, only 5 were considered to be precancerous. This is the most controversial question in breast pathology and will be discussed later.

c Two patients had simple mastectomy done because of such severe pain in one breast that they were literally in danger of becoming narcotic addicts. We have no explanation of this degree of mastodynia but it was not on a neurotic basis in these instances nor were they actual addicts, as both patients were completely relieved. Each had had one or more excisions of painful areas of chronic cystic mastitis before mastectomy and neither had been relieved by hormone therapy.

d This patient had multiple excisions of benign papillary cystadenomas and had multiple tumors when seen in the clinic. The other breast was unaffected. It was obvious that only a mastectomy here could obviate a potentially dangerous situation.

e This patient had multiple, recurrent miniature cystosarcoma phylloides and a mastectomy was the only recourse.

f and g These two groups are self-explanatory and comprise 2 patients in each of which the breast was irreparably damaged by abscesses and chronic draining sinuses.

h This patient had a bulky liposarcoma, diagnosed on biopsy and an extensive complete mastectomy was performed without removal of pectoral muscles or axillary contents.

Group II In this group there are 33 patients who had a simple mastectomy performed because of the presence of a mass in the breast. In some of these patients it is probable that the surgeon suspected carcinoma. None of these patients however were in too poor physical condition to tolerate a radical mastectomy nor were the cancerous lesions advanced when first operated upon.

a. Thirteen patients of this group had carcinoma of the breast and all but two had recurrences when seen in the clinic. These 2 and 4 others who were still operable were

reoperated upon and the surgical therapy converted to a radical mastectomy. The other 7 patients were candidates for palliative radiation only.

b Sixteen patients of this group showed only chronic cystic mastitis in the amputated breasts. The types of mastitis present were not considered significant or necessarily indicative of possible future trouble. Most of these patients were under the age of 40 years.

c, d and e The breasts of 2 patients showed benign papillary cystadenomas, one specimen showed only a solitary cyst of the 'blue-dome' type, and one showed only fat necrosis from a previous injury. This last diagnosis was suspected before operation but the surgeon did a simple mastectomy.

Group III Fourteen patients were subjected to simple mastectomy because of the history of bloody discharge from the nipple. Only one of these had a discrete mass in the breast. This was in a senile patient whose operation was performed under local anesthesia because of her poor physical condition. The mass was minute and pathologically was a low grade intraductal papillary carcinoma with beginning infiltration of the duct wall. Three cases of benign intraductal papillomas were found. None of these showed atypical cytological changes. Ten of the specimens showed only varying degrees of chronic cystic mastitis of no particular prognostic significance.

Group IV In this group 2 patients were subjected to simple mastectomy because of the presence of eczema of the nipple. The specimen from 1 patient, 31 years old showed only eczema. This same patient developed eczema of the remaining nipple several years later and this promptly subsided under dermatologic care. The other patient had true Paget's disease and in the amputated breast there was also a focus of infiltrating duct carcinoma which was palpable before surgery was performed.

Group V One patient is listed who had a simple mastectomy because of a clear discharge from the nipple. No discrete mass was palpable. The breast specimen showed only chronic cystic mastitis of no particular significance.

RESUME

From this review it would seem that in 71 instances of simple mastectomy only 21 were justified. These 21 cases were all direct attempts at eradication of a known disease and in each the diagnosis had been established either by biopsy or clinical recognition of an obvious lesion. These 21 cases comprised 9 of carcinoma, 5 diagnosed as precancerous lesions, 2 of uncontrollable mastodynia, and 1 each of recurrent and multiple papillary cystadenomas, multiple recurrent cystosarcoma phyllodes, tuberculosis of the breast liposarcoma of the breast and chronic draining sinuses of the breast with destruction of the gland.

Six of the patients treated for cancer were such poor surgical risks that only a simple mastectomy was considered justified. Two are untraced, 2 are dead of heart disease, and 2 are alive over 2 years without evidence of recurrence. The 3 patients treated by simple mastectomy as a palliative procedure had varying histories. One had recurrence in the scar in 3 weeks, 1 was dead in 3 months, and 1 is alive and well 8 years. This last is obviously a case of mistaken prognostic estimate as the microscopic sections have been reviewed and verified. Simple mastectomy is useful as a palliative operation to remove bulky ulcerated and fungating masses. Ordinarily x-ray treatment would be expected to follow such a procedure. In many such cases a radical mastectomy will give better palliation than a simple if the lesion is locally operable and axillary metastases are not fixed. The palliative value of a radical mastectomy has not been adequately appreciated or publicized. Actually most radical mastectomies are palliative, in the sense that less than half of all breast cancers so treated are cured although the operation originally was advised as a curative attempt.

The other cases considered to be valid indications for simple mastectomy are largely self-explanatory. The 5 patients who had simple amputation following microscopic diagnosis of a precancerous lesion had diffuse duct changes that were considered to be dangerous enough to warrant extirpation of the breast. Their number in this series is small, but their num-

ber is minute compared to the hundreds of patients having had radical mastectomy and patients having only local excision of benign lesions passing through the tumor clinic.

The 50 patients in this series whose simple mastectomies are considered to have been unnecessary are probably mainly overzealous attempts to be on the safe side. Simple excision of the mass, however, would have accomplished the same thing and in the cancer cases would have afforded less temptation to tamper with the disease. It would seem unnecessary to comment on the seriousness of the error in removing a breast of a younger woman for a benign lesion or equally the error of inadequate surgery for a malignant tumor.

It may be argued that the simple mastectomies done for chronic cystic mastitis were justified from the standpoint of prophylaxis of later cancer, yet the 26 cases listed in Groups II and III were not considered to show precancerous changes. Indications for simple mastectomy are fairly clear when a definite known disease entity is being treated, such as cancer in a poor risk patient, tuberculosis of the breast or cystosarcoma phyllodes. It should be equally clear that this surgical procedure should not be used for diagnostic purposes. The prophylactic aspect of prevention of breast cancer however is a very controversial subject.

The conflict lies, of course, in the definition of what is, and what is not a "pre-cancerous lesion." If we could be certain that a given breast lesion would inevitably become malignant the diagnosis of that lesion would constitute a clear indication for its excision. Theoretically that would not necessarily mean a simple mastectomy. However the only breast diseases that have been implicated in studies of this problem are diffuse changes that involve both breasts, and parts of each breast in varying degree. The conglomeration of pathological changes loosely grouped under the heading "chronic cystic mastitis" are the principal bone of contention in the arguments as to what represents a precancerous lesion. Three of the most intensive recent studies (2, 3, 5) of this problem present somewhat divergent points of view in their details, but

are in agreement on the general principle that more mammary cancer is found in women with chronic cystic mastitis than in females with normal breasts. Such statistical demonstration of relationship does not necessarily imply cause and effect. The pathological changes of chronic cystic mastitis may well be unrelated side-effects of a process which leads to cancer in certain vulnerable areas of epithelium. If the relationship between chronic cystic mastitis and cancer is merely one of association rather than that of stages in a continuous process, then the urgency to eradicate such tissue is less. The pathologic change that has been most closely linked to the development of infiltrating carcinoma is that of duct papillomatosis with cytologic atypism, as described by Foote and Stewart. When this lesion is encountered it may be considered a valid indication for prophylactic simple mastectomy after careful microscopic definition of the tissue. Such lesions shade so imperceptibly into carcinoma *in situ* and ordinary duct cancer that in many instances the differentiation cannot be made.

The problem is still the definition of a pre-cancerous lesion probably one component of the chronic cystic mastitis complex. The authors are in complete agreement with Campbell that the diagnosis of chronic cystic mastitis, the presence of a bleeding nipple, or of intraductal papillomas without cellular atypism do not indicate a prophylactic simple amputation especially in a young woman.

Before any discussion of the value of simple mastectomy it would be well to define this operation. It is usually considered to mean a complete unilateral extirpation of the mammary tissue including the nipple and areola, but without removal of the pectoral muscles or dissection of the axillary contents. Ordinarily a minimal amount of skin is excised.

Actually most simple mastectomies are only partial mastectomies as the breast parenchyma extends far more widely than is generally appreciated. Many so-called radical mastectomies do not remove the breast tissue completely even though the muscles and axillary contents are removed.

Hicken has shown that complete excision of mammary tissue is seldom accomplished in

Fig. 1. Photograph of recurrent, benign, intracystic papilloma occurring 5 years after "simple mastectomy" for similar lesion.

the usual simple mastectomy. His x-ray visualization of the lactiferous ducts has shown that in 95 per cent of the mammary glands studied ducts ascended into the axilla, and some even followed the brachial vessels into the axillary apex. Ducts were found to extend down and medially into the epigastric space in 15 per cent of the cases studied. The ducts also were frequently in intimate contact with the overlying skin and were, on occasions found to cross the midline, pass posterior to the latissimus dorsi muscle border and also penetrate into the substance of the pectoralis major muscle. This excellent study has made it apparent that the majority of our simple mastectomy operations represent only partial or incomplete mastectomies. This is well illustrated by one of our cases in which a mastectomy was performed for an intracystic papilloma. Five years later the patient had a recurrent intracystic papilloma on the same side (Fig. 1).

DISCUSSION

Review of patients having simple mastectomy shows that the operation is uncommonly indicated and is performed too frequently. It is our belief that this procedure should be performed only on the basis of a carefully defined diagnosis. In other words simple amputation of a breast should not be done on suspicion or just in case of doubt unless that doubt is communicated to the patient and

she makes the decision as to acceptance of the risk or elimination by mastectomy. These doubtful situations may be narrowed down considerably by recognition that the only accepted precancerous breast lesions are those duct changes exhibiting atypical hyperplasia to a degree requiring serious consideration of the diagnosis of cancer. Functional changes to a lesser degree or in a different direction can be safely followed without mastectomy by rigid periodic checkups.

Simple mastectomy in other situations would seem to have fairly definite indications. The presence of early cancer in a very poor risk patient is considered to be a worthwhile reason for simple mastectomy. Tuberculosis of the breast with extensive and deep involvement is another recurrent cysto-sarcoma phyllodes or giant intracanalicular adenomyxoma with atypical spindle cell stroma is equally an indication for mastectomy. Occasionally fat necrosis involves the entire breast tissue with sinus formation, local excision of such lesions is impracticable and in fact impossible. Mastodynia of a very severe degree may rarely indicate removal of a breast. Endocrine therapy can relieve, or ameliorate to a bearable degree most of these situations. We believe that simple mastectomy has a very definite but limited place in palliative treatment of advanced breast cancer. Bulky ulcerated masses should be removed but if the axillary involvement is operable and the patient in adequate physical condition a radical mastectomy possibly with skin graft is preferable. Radiation should always be used in palliative problems.

SUMMARY AND CONCLUSIONS

The operation of simple mastectomy is performed far too frequently for benign breast lesions. The usual operation of this type is inadequate and does not remove completely

the breast tissue. Such limited surgery is useful but not when a diffuse lesion of the breast is being treated and particularly not when the operation is done for a "precancerous" lesion as prophylaxis against cancer. Such prophylactic amputation of a breast should be done only on very well considered biopsy material which is interpreted as showing diffuse duct epithelial changes of atypical hyperplasia of a marked degree. We consider the indications for simple mastectomy to be as follows:

1. Therapeutic, when a diagnosed disease of the breast is being treated.
 - a. Palliative for advanced, inoperable breast cancer with a bulky ulcerating mass.
 - b. Palliative for cancer in poor risk patients.
 - c. Sarcoma of the breast.
 - d. Chronic suppurative infections of the breast either non specific or tuberculous, which have destroyed much breast tissue.
 - e. The rare case of uncontrollable and severe mastodynia which does not respond to endocrine therapy and which requires opiates for relief.
 - f. The rare case of diffuse fat necrosis throughout the breast, with sinus formation.
2. Prophylactic.
 - a. Multiple or diffuse, and recurrent benign tumors with malignant potentials such as multiple intracystic papillomas, and cysto-sarcoma phyllodes.
 - b. Precancerous chronic cystic mastitis, showing diffuse duct changes of advanced atypical epithelial hyperplasia.

TRANSABDOMINAL GASTRIC VAGOTOMY

A Study of the Anatomy and Surgery of the Vagus Nerves at the Lower Portion of the Esophagus

LESTER R. DRAGSTEDT Ph.D. M.D., HARRY J. FOURNIER, M.D.,
EDWARD R. WOODWARD M.D. E. BRUCE TOVEE, M.D. and
PAUL V. HARPER, Jr. M.D. Chicago, Illinois

A LARGE variety of surgical procedures for the treatment of peptic ulcer have been introduced since Billroth first devised his epoch making operations on the stomach. With the advent of each new operation fresh impetus has been supplied to a study of the anatomy of the organs and structures involved in the newer techniques. The recent introduction by Dragstedt and his associates (1-5) of complete division of the vagus nerve supply to the stomach as a method of treatment for peptic ulcer has focused the attention of the surgeon and the anatomist alike on the finer anatomy of the vagus nerves and the variations in the distribution of these structures at the lower portion of the esophagus. At the University of Chicago Clinics approximately 300 of these operations have been performed to the present time. The clinical results have been so satisfactory and the complications so transitory and inconsequential that this method has very largely replaced all other types of surgical treatment for this disease in this Clinic. As experience has accumulated the necessity for complete division of the vagus supply to the stomach has become more evident. Physiological tests on 170 patients on whom the operation was performed by us have revealed that the vagus section was probably incomplete in 18 cases. In this group 6 patients have complained of recurrent or persistent ulcer symptoms and in 2 of these, an undamaged vagus fiber was found at a second

operation. Division of this nerve was followed by complete relief. The remaining 164 patients have remained free from all types of ulcer distress on an entirely unrestricted diet and without medication. In general a complete vagotomy is manifested by a profound decrease in the volume and acidity of the continuous night secretion and a negative gastric secretory response to insulin hypoglycemia and the sham meal. It is a striking fact that the excessive continuous night secretion of gastric juice characteristic of patients with duodenal ulcer may be unaffected by the section of two large vagus trunks if a single small vagus fiber is left undisturbed. Section of this remaining fiber may then produce the profound decrease in gastric secretion characteristic of total vagotomy.

The present paper represents the outcome of a co-operative effort carried on in the department of anatomy at the University of Illinois under the direction of Dr. O. Kampmeier and in the department of surgery at the University of Chicago. In the anatomical laboratory a careful dissection was made of the vagus nerves along the lower esophagus in 60 cadavers. Careful records and drawings were made of the variations encountered in the distribution and branches of the right and left vagus nerves along the lower 3 inches of the esophagus and these have been summarized in Figure 1. It is important to note in this drawing that in 81 per cent of cases, the distribution of the anterior and posterior vagus trunks is as illustrated in Figure 1a and Figure 2. Commoner variations are depicted in Figures 1b, 1c, 1d, 1e, 1f, 1g and 1h.

In the laboratories of the department of surgery specimens of the esophagus and stom-

Fig. 1. Sketches showing the distribution of the vagus nerves along the lower portion of the esophagus and upper stomach in 10 human dissection specimens. Note that in 68 per cent of the cases, the distribution is as illustrated in a.

ach were obtained at autopsy from 18 bodies, the vagus nerves carefully dissected and after the dissection the specimens were inflated with air and permitted to dry slowly. The vagus nerves were then colored with white ink to make them stand out sharply in the photographs (Figures 3-12). It is probable that a better understanding of the vagus nerve supply to the stomach can be secured from inspection of the drawings and photographs than could be provided by textual description.

The studies referred to above have been correlated with the less exact observations made at the operating table during the course of division of the vagus nerves to the stomach either by the transthoracic or by the transabdominal approach. In the series of 170 patients in which reliable physiological evidence concerning the completeness of the vagus sec-

Fig. 2. A drawing of a transverse section of the esophagus just below the diaphragm showing the most frequent position of the posterior and of the anterior vagus nerve. Note that both nerve trunks are on the right of the esophagus.

tion is available the operation was performed by the transthoracic approach in 61 patients and by the transabdominal route in 109 patients. Analysis of these data indicates that we were just as successful in securing a complete vagotomy by the transabdominal operation as by exposure of the esophagus in the chest. A careful consideration of the technique employed in the transabdominal operation is however very necessary because it seems very likely that the abdominal methods described by Stierlin, Schlösser, and others would very rarely if ever yield a complete division of the vagus fibers to the stomach. It should be emphasized that in both the transthoracic and in the transabdominal operation, the vagus nerves are divided at a point 2½ to 3 inches above the junction of the esophagus with the stomach. Regardless of the type of approach the operation is a supradiaphragmatic section of the vagus nerves.

A midline incision is made from the xiphoid cartilage to a point 2 or 3 centimeters below the umbilicus. An exploration of the abdomen is then made with especial care to determine the nature and extent of pathology in the stomach and duodenum. If the ulcer is in the duodenum it is important to determine the presence or absence of cicatricial obstruction at the pylorus. Helpful information can be secured by palpation or by the passage of the Levine tube, which is present in the stomach through the pyloric sphincter. If cicatricial obstruction at the pylorus is found the vagus section should be combined with a gastroenterostomy or a gastroduodenostomy. The vagus section is best performed first. While the surgeon makes gentle downward traction on the left lobe of the liver his assistant divides

Fig. 3

Figs. 3-12 Photographs showing the distribution of the vagus nerves to the esophagus and stomach in man. The vagus nerves have been dissected out, colored with white ink, and the stomachs inflated with air before the photo-

graphs were taken. Note that both vagus nerves terminate along the lesser curvature of the stomach, that there are frequent anastomosing branches between them but no true plexus formation.

the triangular ligament with scissors until the lower esophagus is uncovered. The left lobe of the liver is then retracted firmly to the right with a cloth-covered spring retractor. The tube in the stomach facilitates palpation of the lower portion of the esophagus. The peritoneum overlying the esophagus at the margin of the diaphragm is secured with forceps and incised. The scissors are then thrust upward into the mediastinum over the esophagus and the opening enlarged. The index finger is introduced through this opening into the mediastinum and the esophagus mobilized by careful finger dissection. It is important to exercise great care in this dissection since at

least one case has been reported in which the esophagus has been opened. During mobilization of the esophagus in this procedure it is important not to dislocate the vagus trunks by inserting the finger between the nerves and the esophageal wall. If care is taken the nerves as well as the esophagus can be encompassed by the index finger and pulled downward into the abdomen. The vagus trunks are appreciated by palpation as firm, unyielding cords against the more elastic esophageal musculature. The right or posterior trunk is separated from the esophagus with the fingers and pulled around to the left or splenic side of the esophagus. It is usually possible to get

Fig. 7

Fig. 8.

two or three fingers under the nerve trunk in this maneuver thus exposing from $2\frac{1}{2}$ to 3 inches of the nerve. It is our practice to secure this nerve as high as possible with a hemostatic forceps and apply a ligature of nonabsorbable suture material either silk or linen above the hemostat. The nerve is then divided and the distal end pulled downward on the stomach. It is usually possible to excise 2 inches of the trunk for microscopic examination and also as a preventive against subsequent regeneration. The anterior vagus nerve is then separated from the esophagus by a similar maneuver ligated and a portion excised. The longitudinal musculature of the esophagus will now be found to relax somewhat, permitting the esophagus to be pulled still farther into the abdominal cavity. This makes possible the careful inspection of the lower 3 inches of the esophagus, and it is wise at this stage to pick off all strands of fascia and possible nerve fibers with a pair of forceps. In rare cases, a branch of the vagus nerve, either anterior or posterior may be found incorporated in the esophageal musculature or immediately superficial to the mucous membrane. Such branches are readily missed and can be detected only by careful palpation after tension is exerted on the esophagus in several directions. When satisfied that the vagotomy is complete and that hemostasis has been secured the operator closes the opening into the mediastinum with three or four interrupted catgut sutures. The left lobe of

the liver is now replaced but it is usually unnecessary to suture the triangular ligament. If cicatricial obstruction of the pylorus has been found a gastroenterostomy or gastroduodenostomy should now be performed.

POSTOPERATIVE MANAGEMENT

The postoperative care of patients upon whom a total gastric vagotomy has been performed is most important. It is probable that most of the motor disturbances in the stomach that have been encountered are due to failure to appreciate this fact. The mammalian stomach like the heart and the amphibian lung possesses a true peripheral automatism which makes it possible to display its characteristic motor function in the absence of all nervous connections with the central nervous system or even if entirely removed from the body. It is well known that strips of stomach or intestine suspended in oxygenated baths of Ringer's solution or Locke's solution will contract rhythmically for many hours and in response to various types of stimulation. While this is true, under normal conditions, the stomach *in situ* is influenced by two sets of extrinsic nerves the vagi and the sympathetics. These two systems are in constant, but varying tonic activity. While both motor and inhibitory fibers have been demonstrated in the vagus nerves, it is probable that in man, as in the cat and dog, the predominant effect of the vagus on the motility of the cardia is inhibitory. It is motor or augmentor to the

Fig. 9.

Fig. 10.

Fig. 11.

Fig. 12.

antrum and body of the stomach and inhibitory to the pylorus. In general the influence of the sympathetic nerves is antagonistic to that of the vagus. When the vagus effect is then suddenly removed the peripheral motor mechanism of the stomach is subjected only to the activity of the sympathetic nerves and to those humoral influences which come to the stomach by way of the blood stream. If the vagus nerves in the dog are divided high in the chest a marked increase in the tonic activity of the cardia and pylorus is produced which in some cases amounts to a true cardiospasm and pylorospasm. On the other hand the tonus and motility of the body and antrum of the stomach is markedly reduced. Although

we have carefully watched for this complication we have not yet seen a comparable cardiospasm in man following vagotomy from 2 to 3 inches above the stomach. It is possible, however, that vagotomy at a higher level might produce this complication.

It is difficult to determine the presence of pylorospasm in human patients and especially when an ulcer is present in the duodenum. Obstruction at the pylorus could be due to the unopposed motor action of the sympathetic nerves to local spasm or edema or to actual scar tissue narrowing. It is our impression that a pylorospasm comparable to that seen in many dogs following high vagotomy is not commonly seen in the human patient. The

unopposed inhibitory effect of the sympathetic nerves on the tonus and motility of the body of the stomach however makes it easy to produce a marked dilatation and distention of this part of the organ. In the immediate postoperative period this dilatation and distention are most commonly due to the accumulation of swallowed air and gastric and intestinal secretion. Occasionally it may be due to the overingestion of food and drink. Overdistention and dilatation of the stomach markedly delay and interfere with the readjustment of the peripheral motor mechanism and may make the postoperative care of these patients very difficult. If this overdistention of the stomach is prevented a readjustment in the peripheral motor mechanism takes place so that in a relatively short period of time the motor function of the stomach resembles that seen in normal individuals. It is probable that the hypermotility which characterizes many of these patients before vagotomy is never regained. The mechanism of this readjustment after vagotomy is not known. Presumably it might be due to a gradual decrease in the tonic influence of the sympathetic nerves or to an increased activity and influence of the local nerve plexus of Auerbach. While a varying length of time is required by different patients for the peripheral readjustment of the gastric motor mechanism in our experience, the following management has usually been successful.

A Levine tube is introduced through the nose into the stomach from 24 to 48 hours before the operation and the stomach is decompressed by the Wangenstein apparatus. The tube is left in place for 4 or 5 days following the vagus section and great care is observed during this period to make sure that the stomach is completely decompressed. A marked reduction in the volume and acidity of the gastric secretion removed from the stomach after operation as compared with the amount

secured in a comparable period before is a good index of the completeness of the vagotomy. When the tube is removed on the fourth or fifth day the patient is permitted to take 30 cubic centimeters of water per hour for the first day. At the end of the day the stomach is aspirated and if it is empty 60 cubic centimeters of water per hour is permitted for the following day. If aspiration reveals that the larger amount has left the stomach, the patient is placed on a clear liquid diet for 2 or 3 days. The patient is instructed to cease eating if he feels distended. If the liquid diet leaves the stomach satisfactorily semisolid food in small amounts is gradually added. The patient is instructed concerning the alterations in the physiology of the stomach that result from the operation and his co-operation is sought in preventing overdistention in the immediate postoperative period. Some patients have returned to a full diet within 2 to 3 weeks without ill effects, while others more cautious, have voluntarily restricted the intake of food for 5 or 6 weeks. If the stomach has not become overdistended in the immediate postoperative period it is likely that most patients regain normal motor function within 6 months. It is well to bear in mind however that a large ulcer crater in the duodenum may produce cicatricial obstruction on healing that was not observed at the time of the operation. While it is true that urecholine in suitable doses increases the motor activity of the vagotomized human stomach we have not found it necessary or advisable to use this drug in the routine postoperative care of these patients.

MEDIASTINAL CYSTS AND TUMORS

MARTIN L. BRADFORD Major M.C., A.U.S. HUGH W. MAHON Colonel M.C. U.S.A. and
JOHN B. GROW Colonel M.C. U.S.A.

OVER 12 years ago George J. Heuer (26, 28) stated: "The subject of intrathoracic tumors has already become so large that it is difficult to deal with it in a short paper." What he said then of intrathoracic tumors is now true of mediastinal tumors. However, because of the difficulties attendant on diagnosis of mediastinal tumors and the vital necessity of keeping all tumors in mind in differential diagnosis of individual cases, it is well to publish occasional summaries to view more clearly the whole subject. All too often papers are published on benign intrathoracic or mediastinal neoplasms without emphasizing, as John Alexander (5, 6) does, that "The majority of circumscribed intrathoracic neoplasms arise within the lung (almost all of them being malignant); many of those that arise outside the lung are malignant, and therefore the prompt removal of any circumscribed neoplasm which cannot be proved benign is of vital importance."

An adequate classification of mediastinal tumors can be obtained by combining the classifications which were used by Carlson, Laipply, and Heuer (25) in the following manner:

- | | |
|---|---------------------------------|
| I. Congenital cysts | |
| 1. Epidermoid cysts | Ectoderm |
| 2. Dermoid cysts | Ectoderm and mesoderm |
| 3. Teratomas | Ectoderm, endoderm and mesoderm |
| 4. Pericardial celomic cysts | Mesoderm |
| 5. Bronchial cysts | Endoderm and mesoderm |
| 6. Esophageal cyst | Endoderm and mesoderm |
| 7. Gastroenteric cyst | |
| a. Gastric | Endoderm and mesoderm |
| b. Enteric | Endoderm and mesoderm |
| 8. Cystic lymphangioma | Mesoderm |
| II. Acquired cysts | |
| Parasitic cyst, caused by <i>Taenia echinococcus</i> | |
| Neoplastic cyst, due to degeneration of a solid tumor | |
| 3. Cystic hematoma, resulting from degeneration of hematoma | |

From the Surgical and Laboratory Services of Fitzsimons General Hospital, Denver, Colorado

III. Connective tissue tumors

1. Fibromas
2. Lipomas
3. Leiomyomas
4. Xanthomas
5. Chondromas
6. Chondromyxomas
7. Chondromyxosarcomas

IV. Neurogenic tumors

1. Neurofibromas
2. Gangliogliomas
3. Neuroblastomas
4. Neuroepitheliomas

V. Primary tumors of thymus

2. Hodgkin's disease
3. Boeck's sarcoid (?)
4. Endotheliomas

VII. Primary and secondary sarcomas

VIII. Primary and secondary carcinomas

IX. Intrathoracic goiters

A discussion of the symptomatology of such a large group of tumors is virtually impossible, as the individual cases vary from the asymptomatic (by far the largest group) to expectoration of tumor contents and obstructive symptoms causing death. All of the classical symptoms of chest pathology may be present in individual cases, or which is more usual none. The physical examinations too are extremely variable, depending on the size, location, consistency, presence or absence of infection, and extent of involvement of adjacent structures. Roentgenograms are an invaluable aid in this field where physical findings are all too frequently minimal or completely absent. Heuer and Andrus, in their excellent monograph (27) on "The Surgery of Mediastinal Tumors," repeatedly emphasize that surgery is indicated in all mediastinal tumors, not only for treatment but as the only means of positive diagnosis in most cases.

CONGENITAL CYSTS

Epidermoid cysts, dermoid cysts, and teratomas. The first three types of congenital cysts are grouped as one when discussing

Fig. 1

Fig. 2

Fig. 3

Fig. 4

Fig. 4. Postoperative roentgenogram.

their origin. Two plausible hypotheses have been advanced to explain pathogenesis of these tumors, the monogerminal and the bigerminal. Rusby adequately reviews the evolution of these theories and thinks the monogerminal theory is the more reasonable, that the explanation lies in an abnormality of the third and fourth branchial arches, with the abnormal cells being carried into the thorax by the normal descent of the heart and great vessels. He is careful to state that the problem is not yet solved.

Since the original report by Gordon in 1823 to the present time there have been many reviews of this subject in the literature notably Hare (1889) Dangschat (1903) Hertzler (1916) Heuer (1926) Hedblom (1933) and Rusby (1944). In 1945 Lalpally totaled the cases of epidermoids, dermoids, and teratomas at 245 adding a dermoid of his own.

The importance of these tumors lies in the facts that (1) They may cause pressure symptoms as they increase in size. (2) They may become secondarily infected. (3) They may rupture into a bronchus, a blood vessel or the pleura. (4) They may degenerate to malignancy. For these reasons plus the fact that positive diagnosis is impossible in most cases all writers agree that surgical excision is the treatment of choice.

The differentiation between epidermoid, dermoid and teratoma can usually be made grossly if the cyst contents are well defined with adult structures present particularly in the first two; however the microscopic picture will frequently cause the gross diagnosis to be

changed. Epidermoid is the simplest of the cysts lined by stratified squamous epithelium supported by fibrous tissue and its contents are desquamated and degenerated epithelial cells. Dermoid cysts are lined by stratified squamous epithelium with added elements in their walls of structures ordinarily arising from skin: sebaceous glands, coil glands, hair and teeth. The teratomas include elements of all three layers so that all structures of the epidermoid or dermoid may be present plus ciliated and cylindrical cell structures of gut or respiratory tract origin, muscle, bone, cartilage, lymphoid tissue, brain and thyroid.

We offer four cases in this group: 1 dermoid and 3 teratomas.

CASE 1: J. E. H., 23 year old white male, had a routine chest roentgenogram which demonstrated mediastinal tumor. Patient was completely asymptomatic. Physical examination was negative except for slight dullness to percussion and diminution of breath sounds in the anterior right chest extending from the right border of cardiac dullness to the nipple line. Laboratory studies were negative. Roentgenograms showed a circumscribed area of density in the anterior right mediastinum. Fluoroscopy showed no evidence of communication with the vascular system. Thoracotomy and removal of a dermoid cyst in the anterior mediastinum was performed November 9, 1945. Patient was returned to the ward in good condition, and postoperative course was uneventful. Pathological examination of the wall showed a cyst measuring 11 by 10 by 8 centimeters in size from which on cutting a large quantity of yellow turbid material escaped under pressure. There were numerous strands of basophilic squamous epithelium, but no hair as noted. Cyst wall was lined by a flat layer of squamous epithelium and clinging to the surface were numerous lamellations of desquamated squamous epithelium.

Fig. 8. Postoperative roentgenogram showing metastases.

Diagnosis cyst, dermoid thoracic mediastinal right (Figs 1 to 4.)

CASE 3. G. W. A., 30 year old white male, had a routine chest plate which showed an anterior mediastinal tumor. Patient was asymptomatic. Physical examination was negative. Laboratory studies were within normal limits except for the roentgenogram which showed a large mediastinal tumor extending into the right pleural cavity. Fluoroscopy showed no evidence of connection with the vascular system. Exploratory thoracotomy showed a large mediastinal tumor on the right which was removed without difficulty. Patient was returned to the ward in good condition and postoperative course was uneventful. Pathological report showed a 13 by 9 by 8 centimeter cystic mass which on cut section showed

lustrous material with about 490 brown watery fluid in the center howed a dermoid ridge contain

an occasional apocrine present

on of aug

c

in the skull, dorsal spine, lumbar spine or pelvis. There was a circumscribed area of increased density at the neck of the right femur but not suggestive of metastasis, probably normal variation in bone density. Two months after onset of his symptoms he developed malaise, fever, sweats, productive cough with blood tinged sputum and the diagnosis of pneumonia. He recovered from these symptoms following sulfathiazole therapy then he was treated with an unknown amount of deep x ray radiation and the diagnosis of lymphoma, superior mediastinum was made. Following this treatment patient was discharged to return in 6 months for a check up. On return after a 6 months period there was a noticeable enlargement of the tumor mass, and he was transferred to this hospital for further study. On admission to this hospital his only complaint was exertional dyspnea. He had no cough, sputum, hemoptysis or weight loss. Physical examination was essentially negative. Laboratory studies were within normal limits except for the roentgenograms of the chest which showed a circumscribed sharply demarcated tumor in the posterior superior mediastinum extending to the right of the midline pushing the esophagus 2 centimeters to the left of the midline. There was no pulsation of the tumor. Mediastinotomy was performed through a necklace incision the tumor was palpated posterior to the trachea largely to the right. Blunt dissection exposed the tumor its upper cone-shaped wall was free with no thyroid connection. The tumor was removed

It was not attached to any organ, and completely encapsulated. Small cystic areas seen in the cut surface. Immediate recovery operation was uneventful. Two weeks follow

an 8 centimeter mass was felt in the left quadrant medial to spleen. Three weeks later both lung fields contained numerous shadows of homogeneous density $1\frac{1}{2}$ centimeter size diagnosed as metastases. X ray started immediately and the patient total of 900 roentgens through each of four

portals during the next month. His progress was steadily downhill and he expired 3 months following surgery. Pathological report showed that the tumor appeared to be a solid teratomatous tumor (mixed tumor) of mediastinum. Areas in it were so cellular as to suggest bone carcinoma and sarcoma depending on the area observed and the cell type that had proliferated. Mitosis were occasionally seen. They seemed confined to the connective tissue cell. Diagnosis: teratoma, tumor of the mediastinum, malignant (Figs. 5 to 8).

CASE 4. J. P. O. M. 32 year old white male was well until 8 months previous to admission when he noticed a dull ache in the left shoulder which gradually became worse until it kept him awake at night. His symptoms were never severe enough to require hospitalization or examination by a physician. While at a separation center a routine roentgenogram showed a mass in the left upper mediastinum. Physical examination showed a visible and palpable pulsation synchronous with systole in the second left interspace. The mediastinum was widened to percussion in this area. Fluoroscopy showed a nonexpansive, left anterior mediastinal tumor with some plaque like calcification in the lateral wall. Esophagus was negative. Exploratory thoracotomy showed a large mediastinal teratoma located in the left anterior mediastinum extending upward into the root of the neck. The mass was completely removed. Patient returned to the ward in good condition. Postoperative course was uneventful. Pathological examination of tissue showed a fragmented cystic structure weighing 133 grams with irregularly sized, round to oval pedunculated tissue masses covered with pale squamous epithelium from which numerous pale hairs protruded. The cyst wall was flattened and covered with sebaceous material. Grossly no bone teeth or definitely teratomatous tissues were encountered. Microscopic section showed the lining of the cavity composed of a layer of squamous epithelium varying slightly in width. There were acini of mucous glands closely resembling those seen in the bronchus. In other areas, tubules lined by tall

columnar ciliated cells were seen with occasional goblet cells in the wall. There are bundles of smooth muscles associated with these tubules and occasional glandular structures. One small amorphous of calcified material was seen which may have been bone. Diagnosis: teratoma, cystic, mediastinal, benign, dermoid features predominating (Figs. 9 to 12).

Pericardial celomic cysts. The thin-walled cysts of the mediastinum have caused some discussion since Churchill described the findings at operation in Cabot's Case 23492. He did not mention the term "spring water" cysts at that time, but the name is now attributed to him. Mallory gave the pathological report on the same case, describing the cyst lining as "mesothelium" with the cells ordinarily so thin that they can hardly be distinguished from endothelium, but they occasionally thicken up to a cuboidal type of cell that looks quite like epithelium.

Lambert seems to have adequately explained the origin of these cysts in his theory of failure of one of the primitive pericardial lacunae to merge with the others, thereby forming a cyst. If we can combine the "spring water" cysts and the "pericardial celomic" cysts reported (Dufour H. and Nourret, 1939; Pickhardt O. C. 1934; Churchill, E. D. 1937; Lambert A. V. S. 1940; Greenfield L. et al. 1943) there are only 7 that meet the requirements of (1) a thin walled cyst, (2) clear fluid, (3) a lining membrane of endothelium or mesothelium that may look quite like epithelium. Seven seems entirely too few cases to be reported as we have 8 that meet the

Fig. 16. Showing simple fibrous wall with surrounding fat. 1. Epithelium is denuded.

above aorta. Possibly when the present confusion regarding classification is settled more cases will be reported.

CASE 5. I. H. B., 30 year old white male noted a sensation of pressure and fullness in the epigastric region 2 months previous to admission. There was very slight dyspnea on exertion otherwise asymptomatic. Physical examination was negative. Laboratory studies were negative except for the chest roentgenogram which showed a well circumscribed opacity at the cardiophrenic angle on the right. Exploratory thoracotomy showed a cystic lesion attached by a pedicle to the pericardial phrenic angle and it was easily removed. Recovery from operation was uneventful. Pathological report showed a cystic lesion measuring 8.5 by 5.5 by 7 centimeters in diameter with absolutely clear fluid and a very thin wall so that newsprint could be read through the specimen. Microscopic section showed the inner surface lined with flat epithelium and an occasional area composed of a few cuboidal cells. The cells rested on a hyaline membrane varying slightly in thickness and appearing to be composed of connective tissue. No squamous epithelial structures were noted in the wall and there was no ciliated epithelium. Diagnosis: cyst simple, pericardial (celomic) mediastinum right.

CASE 6. T. C. K., a 45 year old white male who complained of pain in the left chest, dyspnea, malaise and productive cough of 4 months duration. There was a weight loss of 12 pounds in the past 2 months. Physical examination was essentially negative. Laboratory tests were negative except for roentgenogram of the chest which showed a well circumscribed dense mass in the left lower lung field. Exploratory thoracotomy showed a large cyst occupying the angle between the diaphragm and the pericardium with a broad attachment to the pericardium. The cyst was dissected free and removed by blunt and sharp dissection. Recovery from the operation was uneventful. Pathological report

showed a cyst with no epithelial lining. The walls were composed of acellular fibrous lamellae with some hyalinization and in one section granular calcium disposition in a small area of degeneration of fibrous tissue. A serous layer covered the outer surface apparently pleura. Diagnosis: cyst serous unilateral intrathoracic left.

CASE 7. O. F. K., a 32 year old white male had a routine chest plate which showed an opacity in the medial and anterior portion of the right chest contiguous with the diaphragm. History and physical examination were completely negative. Laboratory tests were completely negative except for the roentgenogram which showed a well demarcated elliptical soft tissue mass in the right cardiophrenic area anteriorly. Gastrointestinal series was negative. Thoracotomy showed a clear thin walled cyst containing approximately 100 cubic centimeters of clear fluid freely movable and attached by a pedicle to the cardiophrenic angle. The cyst was removed, the patient returned to the ward in good condition and recovery was uneventful. Pathological report showed the cyst containing crystal clear fluid and newsprint was easily read through the cyst. Microscopic section of the cyst wall was thin and composed of parallel hyaline connective tissue fibers. Lining cells were flattened and no evidence of cilia was seen. Diagnosis: cyst spring water (celomic) mediastinum right.

CASE 8. R. S. S. This 27 year old white male had a routine roentgenogram of the chest which showed evidence of mediastinal tumor. History was completely negative. Physical examination showed a slight limitation of motion of the right chest with a flat percussion note in the lateral aspect of the right base. Breath sounds were diminished in this area, and tactile fremitus was decreased. The rest of the physical examination was normal. Laboratory examinations were within normal limits except for the roentgenogram which showed a well circumscribed density between the right middle and lower lobes. These findings were suggestive of a benign, cystic,

Fig. 8. Opened gross specimen

Fig. 9. Showing ciliated columnar epithelium

Fig. 10. Postoperative roentgenogram.

tumor thought to be attached to the diaphragm or the pericardium. Thoracotomy showed a cyst attached to the cardiophrenic angle by a 2 inch pedicle. The cyst was easily removed. The thorax was closed. Patient returned to the ward in good condition. Recovery was uneventful. Pathological report showed a clear cyst about 8 centimeters in diameter with a thin wall composed of connective tissue with flat epithelium without cilia lining the cyst. Diagnosis: cyst pericardial, (celomic) mediastinum, right.

CASE 9. R. R. DIF. This 31 year old white male complained of vague pains in the epigastrium and upper left quadrant of the abdomen when he ate meat or became nervous. The pains were more severe when the patient was lying down. Duration of symptoms was unknown. Physical examination was negative except for decreased excursion of the left diaphragm which seemed high and immobile. Laboratory examinations were within normal limits with the exception of roentgenograms which revealed an abnormal mass in the left chest which was thought to be a diaphragmatic hernia. Diagnostic studies ruled out a diaphragmatic hernia, and the mass was thought to be primary in the left thorax. Thoracotomy was performed, and a cyst was removed. Pathological report showed a roughly pyramidal cyst measuring 11 by 7 by 7 centimeters with a clear thin wall. Approximately 250 cubic centimeters of thin crystal-colored fluid was evacuated from the cyst. Sections of the cyst wall showed the wall to be composed of laminated connective tissue, the lining of ciliated epithelium. The impression of the pathologist was that this was a mediastinal cyst which has been designated under numerous terms such as cystic lymphangioma, cystic hygroma, ciliated epithelial cyst or spring water cyst of Churchill. Pathological diagnosis: cyst mediastinal probably spring water.

CASE 10. P. B. This 29 year old colored male was completely asymptomatic but was told he had a chest tumor following a routine roentgenogram. Physical examination was essentially negative. Routine laboratory examinations were within normal limits. Roent-

genogram of the chest showed an opaque triangular density in the region of the middle lobe on the right. **Impressions.** Pericardial cyst. Bronchoscopy showed no evidence of endobronchial pathology. On September 5, 1946 right thoracotomy showed a pericardial cysts attached to the anterior cardiophrenic angle, this was easily removed intact. Postoperative course was entirely uneventful. Patient was returned to full duty. Pathological examination showed a pear-shaped fluid-filled cyst weighing 210 grams containing 180 cubic centimeters of crystal clear watery fluid, specific gravity 1.009. Cyst measured 4 by 6 by 7 1/2 centimeters. Microscopic section showed the wall of the cyst formed by compact fibrous tissue. In places there was an outer layer of adult fat. It appeared to replace most of the thickness of the fibrous wall there was some loose scattering of lymphoid cells usually in the fat near a junction with the fibrous wall, and occasional small, flattened-out collections of lymphocytes. No definite Hassell's corpuscles were seen in such areas. A single layer of flattened cells lines the cystic spaces. Occasionally these cells seemed thicker oval no cartilage was seen in the walls. Diagnosis: pericardial cyst, celomic type.

CASE 11. R. F. A. This 33 year old white male was completely asymptomatic. Routine roentgenogram demonstrated a tumor in the right lower chest just above the diaphragm. On admission to this hospital examination revealed decrease of the breath sounds over the right lung field, more noticeable anteriorly, there was very slight dullness of the right lung field in this region. Routine laboratory examinations were within normal limits, roentgenogram of the chest revealed a fairly well circumscribed density in the right supra-diaphragmatic region in the cardiophrenic angle appearing to be contiguous to the diaphragm. Thoracotomy with removal of the pericardial cysts was performed and recovery was uneventful. Pathological report showed a 10 1/2 by 9 1/2 by 6 1/2 centimeters transparent cyst filled with 200 cubic centimeters of clear watery fluid having a specific gravity of 1.007. Microscopic section showed the walls of the cyst to be fibrous, loosely arranged

Fig. 21

Fig. 23.

Fig. 21. Preoperative esophagram. Case 18.

Fig. 22. Showing ciliated columnar epithelium.

Fig. 23. Postoperative esophagram.

and relatively acellular. The inner surface of the wall was lined by a single layer of slightly flattened cuboidal cells having dark staining oval nuclei. Diagnosis: Pericardial cyst, celomic.

CASE 12. E. L. A. This 34 year old white male was completely asymptomatic but a routine roentgenogram revealed a mass in the left lower lung field. On admission physical examination was negative except for examination of the chest which revealed dullness at the right base anteriorly up to the third rib. Tactile fremitus was absent at the right base. Breath sounds were normal except for this area where they were diminished to absent. Roentgenogram of the chest revealed an elliptical soft tissue mass in the anterior right thorax probably adherent to the pericardium and to the medial portion of the diaphragm. Routine laboratory studies were within normal limits. Bronchoscopy was negative. Bronchograms showed the filling defect apparently external to the pulmonary parenchyma. Exploratory thoracotomy revealed a large pericardial cyst which was easily removed. Recovery from surgery was uneventful. Pathological report showed a 12.5 by 11 by 6 centimeter cyst containing about 300 cubic centimeters of clear colorless fluid. Wall was paper thin. The cyst was unilocular with several paper thin, low baffle like ridges which could be seen as white fibrous bands through the outer surface. Microscopic showed no epithelial lining although occasional flat cells were seen as if the cysts had been lined by endothelium-like membrane. The wall was composed of acellular strands of connective tissue with fat present in half of the wall close to its original attachment to the mediastinum. A few small collections of lymphocytes were scattered in the wall. The outer surface was covered by a very thin fibrous membrane suggesting mediastinal pleura. Diagnosis: mediastinal cyst (pericardial celomic, congenital) (Figs 13 to 16).

Bronchial cysts of the mediastinum. These congenital cysts of the mediastinum are char-

acterized by ciliated columnar epithelium in their lining membranes. They are of endodermal and mesodermal origin and are generally supposed to arise from the pinching off of a bit of the foregut or tracheal bud which is carried into the mediastinum by the lungs. Cartilage and smooth muscle bundles are frequently present in their walls and the characteristic cellular lining is frequently destroyed by the pressure of the contained fluid, making diagnosis difficult in some cases unless many microscopic sections are taken to find characteristic epithelium in an untouched recess of the cyst. Treatment is complete excision if possible but Adams and Thornton (1943) reported good results in 2 cases following partial excision with destruction of the remaining lining mucosa. Laipply (1945) summarized the literature and with a case of his own reported a total of 35 cases.

We have 5 bronchial cysts of the mediastinum.

CASE 13. R. E. D. This 25 year old white male had a routine chest roentgenogram which showed a mediastinal tumor. Patient was completely asymptomatic. Physical examination was negative. Laboratory studies were within normal limits except roentgenograms of the chest which showed a large mediastinal mass on the right. Esophagram showed displacement of esophagus to the left by the posterior mediastinal mass. On thoracotomy a large cystic tumor of the posterior mediastinum was found that lay posterior to the base of the heart and anterior to the esophagus. The cyst was evacuated and the entire cyst wall was removed from the mediastinum *in toto*. Before it was opened, the cyst

Fig. 36. Microscopic section showing fat cells

Fig. 7. Postoperative roentgenogram

measured approximately 15 centimeters in length and 8 centimeters in its greatest diameter. Postoperative course was uneventful. Pathological report showed one section of the cyst wall lined by ciliated columnar epithelium typical of that seen in the respiratory tract. The back of the wall was composed of a plate of hyaline cartilage and interposed between it and the respiratory epithelium were flattened mucous glands. Diagnosis cyst, ciliated, congenital, bronchogenic type, mediastinum.

CASE 14. C. L. S. This 24 year old white male noted chest pain and cough productive of large amounts of sputum 5 months previous to admission. One month after onset a chest roentgenogram revealed a large opacity in the lower lobe of the left lung. Diagnosis at that time was empyema with a bronchopleural fistula, left. Treatment was conservative during the first 5 months of his illness. On admission to this hospital, patient had been coughing up large amounts of mucopurulent sputum during the previous 5 months, with occasional episodes of moderate fever with temperatures running to 101 degrees. He had an indefinite pain in his left chest, transitory in type never severe. Physical examination was essentially negative except for moderate weight loss, dullness to percussion and absent breath sounds over the left base both anteriorly and posteriorly. A thoracotomy with drainage of a large abscess cavity in the lower portion of the left thorax was performed. A biopsy of the abscessed wall at that time showed a cyst lined with respiratory epithelium, ciliated. It was felt at the time that the patient had an intrapulmonary bronchogenic cyst, and he was treated conservatively for 3 months. At the end of that time an exploratory thoracotomy was performed and it was found that the cyst was extra pleural, and originating in the mediastinum. It was dissected free from the left lower lobe and the diaphragm, and amputated from its medial attachments in the mediastinum. The excised specimen collapsed, measured approximately 0.5 centimeters in diameter. Recovery was uneventful, and the left lung completely expanded (Figs. 7 to 10.)

CASE 15. E. F. This 25 year old colored male was asymptomatic. On routine chest roentgenogram, a mediastinal tumor was discovered. Physical examination was negative except for an area of dullness to percussion over the right anterior thorax extending about 8 centimeters from the midsternal line in the 5th intercostal space. Roentgenogram of the chest revealed a right mediastinal tumor area located between the spine and the heart, displacing the esophagus to the left. The carina was somewhat widened. Exploratory thoracotomy showed a large cystic mass about 8 by 8 by 10 centimeters in size lying behind the bifurcation of the trachea, and anterior to the esophagus. The contents were evacuated, and a cystic sac excised *in toto*. Recovery from surgery was uneventful. Pathological report showed the cyst wall to be composed of partially desquamated layer of ciliated epithelium. The wall contained bundles of smooth muscle which were hypertrophied in some areas, and in other areas the sub-epithelial tissues were composed of diffuse sheets of hyaline material. Diagnosis cyst bronchogenic, ciliated, mediastinum.

CASE 16. A. H. B. This 3 year old black male was well until 2 months previous to admission when he had bilateral infectious parotitis complicated by pneumonia. The pneumonia responded well to penicillin therapy but after recovery from the acute symptoms a large circumscribed intrathoracic tumor was discovered on the roentgenogram examination. On admission to this hospital, he was completely asymptomatic. Physical examination was negative. Laboratory studies were within normal limits with the exception of the roentgenograms of the chest which showed a large tumor mass in the base of the left lung, the heart shadow overlying most of it. It was located in the posterior portion of the left chest extending over to the posterior mediastinum. There had been no change in size since the previous film taken months before admission. Thoracotomy showed a large cystic mass at the base of the left lung seeming to originate in the posterior mediastinum below the hilum of the left lung. The cyst

Fig 30

markedly adherent to the left lung and to the left diaphragm. By blunt and sharp dissection the cyst was removed *in toto*. The thorax was closed and the patient returned to the ward in good condition. Postoperative course was uneventful with the exception of a transient atelectasis which was treated by bronchoscopy on the second postoperative day. Pathological report showed a large cyst approximately 12 centimeters in diameter with a shaggy external surface caused by numerous fibrous adhesions. The cyst was filled with a yellowish clear fluid and sections through the wall showed plates of hyaline cartilage and the cyst lined with respiratory epithelium, ciliated. Diagnosis: cyst bronchogenic ciliated mediastinum.

CASE 17. B. I. J. This 22 year old white male had mild intermittent chest pain of 6 years duration. Roentgenograms taken during the 6 year period were reported alternately as showing "tumor" in the chest and negative. In 1943 he was rejected by the Army but in 1944 was admitted to the Army. He completed basic training and served on combat duty 8 months in the European Theater. At the termination of this time he complained of chest pains however roentgenograms were read as negative. During a routine chest examination while undergoing separation roentgenograms were interpreted as showing neoplasm upper mediastinum, nonmalignant. On admission to Fitzsimons General Hospital physical examination was essentially negative except for soft rales in the right upper chest anteriorly. No evidence of cavitation or consolida-

tion was found on physical examination. Roentgenograms showed a sharply circumscribed tumor mass in the right superior mediastinum with minimal fibrosis at the left apex. Routine laboratory studies were within normal limits. Bronchoscopy was negative. On May 22, 1946 thoracotomy revealed that a mediastinal bronchogenic cyst which was easily removed. Recovery from surgery was uneventful. Pathological report showed a cyst measuring 3.5 by 2.8 by 2.3 centimeters containing very thick jelly like mucus lining was irregular greyish with scattered small, milk white hyalinized bosses. A circular ridge extended from the first ridge to one pole. These ridges were rubbery firm and felt as if they might contain small cartilaginous plates. Microscopic examination showed an outer zone of loose, fibrous tissue with blood vessels and occasional nerves where the cyst was embedded elsewhere the outer surface was covered by thin mediastinal pleura. Cyst wall within was composed of dense compact, hyalinized fibrous tissue covered by a thin flattened epithelium thick portions of the wall consisted of thick bundles of smooth muscle cells with a few mucous glands and ducts between the muscle layers lining epithelium in these areas was ciliated pseudostratified cylindrical epithelium. In one area the epithelium was lost and here the cells of underlying stroma showed xanthomatous degeneration. Small collections of lymphocytes are scattered through the wall and in the midzone usually around the engorged capillaries. Diagnosis: bronchogenic cyst congenital.

Esophageal cysts and gastroenteric cysts

These cysts are discussed under one heading because of their similar embryonic origin. Olken in his excellent review in 1944 summarized three possible explanations for these cysts: (1) pinching off a bud or diverticulum of the embryonic foregut; (2) an intrathoracic remnant of the omphalomesenteric duct; and (3) an embryonic diverticulum or epithelial remnant capable of producing intestinal or gastric mucosa.

Esophageal cysts would be expected to have a stratified squamous epithelium lining. However, since esophageal cysts are remnants of the embryonic esophagus, which has ciliated epithelium, it is reasonable to assume that the cysts could maintain the primitive lining instead of assuming the lining found in the developed esophagus. The possibility that these cysts, in close association with the esophagus, are of bronchial origin cannot be ignored because at the time of separation of the lung buds from the primitive esophagus, the pinching off of an outbud could occur and become engulfed in the growing esophagus. Therefore, the gross location of these cysts will have to determine their origin: those included within the muscularis of the esophagus can be called esophageal cysts; those located in the rest of the mediastinum or lung can be of bronchial origin. Frequently in bronchiogenic cysts cartilage is found in the cyst wall. We present one case in this group that of a ciliated pseudostratified columnar epithelium

line cyst that was located between the mucosa and the muscularis of the esophagus.

CASE 18. A. J. P., a 22 year old white male, has complained of "water-brash" and regurgitation a food of 6 years duration. While in combat his father and roentgenograms showed a pressure defect in the esophagus. The patient was returned to the zone in the interior where roentgenograms confirmed a slight pressure defect in the lower third of the esophagus. Thoracotomy showed an esophageal cyst located between the mucosa and the muscular layers. The cyst was enucleated without entering the lumen of the esophagus. It contained fluid. Pathological report showed a cyst with ciliated epithelial lining. Diagnosis: ciliated cyst esophageal, congenital (Fig. 31-33).

Gastroenteric cysts are characterized by the resemblance to gastric and intestinal structures. They are rare with only 19 cases found by Olken including 1 of his own; 5 more reported by Ladd and Scott, and 1 by Lappley. All but 3 were in children under 2 years of age. Ladd and Scott had recovery in 3 cases following marsupialization of the cyst and subsequent destruction of its mucosal lining.

Cystic lymphangiomas. These tumors are also called "cystic hygromas." They are extremely rare in the mediastinum. Sames and associates were able to collect 8 cases from American and foreign literature, including 2 cases of their own. Cystic lymphangiomas are characterized by multiloculated cysts containing fluid with an endothelial lining and smooth muscle and lymphocytes in the walls.

Fig. 39. Postoperative esophagram.

ACQUIRED CYSTS

This group of cysts is mentioned mainly to be kept in mind in differential diagnosis. Echinococcus cysts of the mediastinum are extremely rare compared to the same type of cyst of the lung. Neoplastic cysts are due to degeneration of a solid tumor and any solid tumor in this classification may show these characteristics more usually the highly malignant types. Hemothorax, other than traumatic, can come from rupture of an aneurysm degeneration of a neoplasm, or spontaneous hemopneumothorax. In unusual cases they may simulate mediastinal tumors.

CONNECTIVE TISSUE TUMORS

Fibromas In 1941 Blades reported 32 cases of intrathoracic fibromas in the world literature indicating the rarity of the lesion. Of these cases 18 died of pressure symptoms unoperated upon and of the 14 cases in which operation was done all lived except one. Clagett and Hausmann (14) successfully removed a 10.9 pound fibroma which they claimed to be the largest intrathoracic tumor ever removed surgically with survival and complete recovery of the patient. Of the 18 cases collected by Heuer and Andrus (28) in 1933 only 5 below the age of 40 had symptoms suggesting that these tumors are silent for years before symptoms occur.

Lipomas Most of the intrathoracic lipomas originate in the mediastinum as evi-

denced by Heuer's report (26) in 1933 on 29 cases—25 occupied the mediastinum and 4 were subpleural. They may attain giant size and cause death from pressure symptoms. In Heuer's case the tumor filled the entire left hemithorax with displacement of heart and mediastinal contents far to the right. McCorkle and associates collected 34 cases in 1940 and of these only 12 were successfully excised. Watson and Urban and Wiper and Miller each have added successful cases (undoubtedly there are more). We have 3 cases of successful extirpation of a mediastinal lipoma.

CASE 19. R. R. D., a 37 year old white male had a routine chest roentgenogram which showed a mediastinal mass. History and physical examination were completely negative. Laboratory studies were negative with the exception of roentgenograms of the chest which showed an ovoid tumor mass anteriorly in the right cardiophrenic angle considered to be possibly a dermoid or substernal diaphragmatic hernia. A gastrointestinal series showed a herniation of the stomach or bowel through the diaphragm. Thoracotomy showed a fatty tumor mass approximately 5 centimeters in diameter located in the cardiophrenic angle on the right. This was easily removed. Patient returned to the ward in good condition and recovery was uneventful. Pathological report showed a lobulated adipose mass. No noteworthy pathology was seen.

CASE 20. R. L. H., a 30 year old white male had a mediastinal mass which was seen on routine roentgenogram of the chest. History and physical examination were completely negative. Laboratory studies were negative with the exception of roent-

Esophageal cysts and gastroenteric cysts
These cysts are discussed under one heading because of their similar embryonic origin. Olken in his excellent review in 1944 summarized three possible explanations for these cysts: (1) pinching off a bud or diverticulum of the embryonic foregut; (2) an intrathoracic remnant of the omphalomesenteric duct; and (3) an embryonic diverticulum or epithelial remnant capable of producing intestinal or gastric mucosa.

Esophageal cysts would be expected to have a stratified squamous epithelium lining. However, since esophageal cysts are remnants of the embryonic esophagus which has ciliated epithelium, it is reasonable to assume that the cysts could maintain the primitive lining instead of assuming the lining found in the developed esophagus. The possibility that these cysts, in close association with the esophagus, are of bronchial origin cannot be ignored because at the time of separation of the lung buds from the primitive esophagus the pinching off of an outbud could occur and become engulfed in the growing esophagus. Therefore the gross location of these cysts will have to determine their origin: those included within the muscularis of the esophagus can be called esophageal cysts; those located in the rest of the mediastinum or lung can be of bronchial origin. Frequently in bronchogenic cysts cartilage is found in the cyst wall. We present one case in this group that of a ciliated pseudostratified columnar epithelium

line cyst that was located between the mucosa and the muscularis of the esophagus.

CASE 18. A J. P., a 22 year old white male, had complained of "water brash" and regurgitation of food of 6 years' duration. While in combat he failed and roentgenograms showed a pressure defect in the esophagus. The patient was returned to the zone of the interior where roentgenograms confirmed a single pressure defect in the lower third of the esophagus. Thoracotomy showed an esophageal cyst located between the mucosa and the muscular layers. The cyst was enucleated without entering the lumen of the esophagus. It contained fluid. Pathological report showed a cyst with ciliated epithelial lining. Diagnosis: ciliated cyst, esophageal, congenital. (Figs 21-23.)

Gastroenteric cysts are characterized by the resemblance to gastric and intestinal structures. They are rare, with only 19 cases found by Olken including 1 of his own, 5 more reported by Ladd and Scott and 1 by Lapp. All but 3 were in children under 2 years of age. Ladd and Scott had recovery in 3 cases following marsupialization of the cyst and subsequent destruction of its mucosal lining.

Cystic lymphangiomas These tumors are also called cystic hygromas. They are extremely rare in the mediastinum. Sances and associates were able to collect 8 cases from American and foreign literature including a case of their own. Cystic lymphangiomas are characterized by multiloculated cysts containing fluid with an endothelial lining and smooth muscle and lymphocytes in the walls.

genograms which showed a mass to the right of the cardiac shadow in the cardiophrenic angle which appeared to be a pericardial cyst. Thoracotomy was performed and the mass was easily removed. Recovery was uneventful. Pathological report showed an irregular oval mass 6 by 5 by 5 centimeters enclosed in a transparent fibrous capsule. Microscopic section showed uniform picture of adult fat cells with fine widely spaced fibrous strands outlining indefinite lobules. Diagnosis: lipoma, adult sized type, mediastinum.

CASE 31. T. H. P. This 44 year old white male was admitted to the hospital complaining of symptoms referable to an indirect inguinal hernia. On routine roentgenograms of the chest, a mediastinal tumor was discovered. History of any chest complaints was completely negative. Physical examination was essentially negative. Laboratory studies were within normal limits with the exception of the chest roentgenogram which showed a rounded shadow sharply circumscribed inferiorly and laterally seen in the right chest suggesting a cyst. The shadow lay posteriorly. Lung markings traversed the area anterior to the mass. The tumor was not so dense as to obliterate the rib markings. Fluoroscopy showed no connection to the cardiovascular elements although the medial attachment of the tumor could not be rotated away from the hilar or mediastinal shadows. There was no pulsation in the tumor. Exploratory thoracotomy through a right Sauerbruch thoracoplastic incision showed a large circumscribed fatty tumor mass. This was removed, the chest closed and recovery from surgery was uneventful. Pathological report showed an oval flabby undurated yellow fat tumor weighing 225 grams, measuring 11 by 8.5 by 6.5 centimeters in diameter. Microscopic section showed the tumor to be composed for the most part of adult fat cells, but in some areas the appearance was more cellular with an increased number of spindle cells and fibrocytes and with fat cells that appeared partially collapsed and slightly opaque. No mitoses were seen. Diagnosis: lipoma.

mediastinal, growing into right pleura, benign (Figs. 24-27).

The mixed types of fatty tumors would come under this heading such as the fibrolipomas and fibrolipomyxomas. We have one case of fibrolipomyxoma that was operated upon in 1942 but had recurrence bilaterally in 1944. In a two stage procedure, operating on both sides the tumor was apparently removed.

CASE 32. D. E. G. This 38 year old colored male was first operated upon by Dr. Thomas J. Knudsen, of Minneapolis. He had a mediastinal tumor known for 18 months which measured 11 by 16 by 16 centimeters at the time of operation. The tumor was removed from the right posterior chest and mediastinum and the gross specimen appeared to be well encapsulated but Dr. Knudsen felt that recurrence probably would occur. The pathological diagnosis was benign degenerating fibroma. Two and one-half years following his first operation, he was admitted to this hospital complaining of epigastric distress which was consistent with the diagnosis of duodenal ulcer. During his routine stomach x-ray a plate was taken which showed multiple, small round tumor masses in the cardiophrenic angles, bilateral. Thoracotomy was performed on the right, and multiple tumor masses were removed from along the sympathetic chain on the right—the largest measured 10 by 6 centimeters in diameter. One of the masses was almost gelatinous in character, and the operator felt that it was not removed entirely. Two and one-half months after the first operation at this hospital, thoracotomy on the left was performed and four distinct tumor masses were removed from the mediastinum in the region of the sympathetic chain and ganglia. Three nerves passed into the tumor masses. Grossly it was felt that these masses had their origin in nerve tissue. Recovery from both operations was uneventful except for mild

atelectasis which developed on the second postoperative day following the second operation and which was treated by bronchoscopic aspiration. Check-up plates taken a month postoperatively showed no evidence of tumor masses remaining in the mediastinum. Patient was advised that he would have probable recurrence and should have frequent x ray examinations of his chest in the future. Pathological report on all tumor masses was identical. Microscopic sections showed adipose tissue with irregular walls many of the cell processes appeared to be going on into a myxomatous type of degeneration and the cells were stellate with hypochromatic nuclei and interlacing cytoplasmic fibrils. No mitotic figures were seen nor were there sheets of cells. At the periphery of one section the spindle cells and occasional stellate cells were more numerous appearing to form a capsule. Impression: Tumors appeared to be benign and encapsulated and apparently were myxomatous degeneration of lipid tissue. Diagnosis: myxolipoma benign. (Note: Dr Thomas J. Kinsella has reviewed all slides and agrees that the original diagnosis from the specimen taken by him should be myxolipoma, benign.) (Figs 28 to 35)

Leiomyomas These tumors can occur in the mediastinum, but diagnosis is impossible until biopsy is performed preferably at the time of total excision of the mass. It is important to remove them because of the possibility of sarcomatous degeneration in this type. An interesting case in our series showed multiple pressure defects of almost the entire intrathoracic esophagus, with intact mucosa on esophagoscopy. At operation 14 intramural extramucosal tumors of the esophagus were removed which proved to be leiomyomas on microscopic section.

CASE 23. C. S. A 33 year old white male complained of substernal pain on swallowing of 2½ years duration and a sensation of pressure defects in the esophagus. Esophagoscopy confirmed the multiple pressure defects and stated they were all extraluminal. No evidence of ulceration in any area was seen. Physical examination and laboratory studies were within normal limits. Thoracotomy showed multiple tumor nodules along the entire length of the thoracic esophagus, varying in size from about 4 centimeters to 1 centimeter. One of these masses was removed for a frozen section. Pathological report was leiomyoma of the esophagus. A total of 14 esophagus tumors were removed the tumors were located in and beneath the musculature of the esophagus, but caused no erosion of the mucous membrane. At no time was the lumen of the esophagus entered. Recovery from the operation was uneventful. Pathological diagnosis: multiple leiomyomas of the esophagus (Figs 36 to 39).

Xanthomas These tumors occur in the mediastinum as elsewhere in the body. They are considered benign but may go on to form xanthosarcomas. Heuer and Andrus (26) collected only 10 cases of this type in 1940 including 2 of Dr Heuer's. The tumors occurred only in adults and all 10 were successfully removed. It is questionable that these tumors should be considered as a separate type as they seem to be more of a degeneration process in tumors such as lipomas and fibromas.

Chondromas **Chondromyxomas** **Chondrosarcomas** These tumors originate from cartilage which is found adjacent to the mediastinum in the sternum costal cartilages

and articular surfaces of the spine and costo-vertebral junctions. They are important in that they attain great size and may metastasize even though benign on microscopic section. Heuer and Andrus (27) found in the literature since 1926 only 14 that involved the mediastinum. Surgical removal is indicated as they do not respond to radiation therapy and resection is facilitated by the infrequency of invasion of surrounding structures.

NEUROGENIC TUMORS

Pathological discussions of neurogenic tumors are based on work done by Von Fischer and Kuntz. These tumors arise from the sympathetic nervous chain or its anlagen and are manifestations of the development from the original medullary epithelium. As the cells migrate from the ganglionic crest they may form cell rests at various stages in their development which proliferate to form the neurogenic tumors. Using the chart published by Andrus in 1937 a simplified method of showing the origin of the thoracic neurogenic tumors is presented.

Medullary epithelium	→ Neuroepitheliomas
Ganglionic crest	→ Neuroepitheliomas
Migrating undifferentiated cell	→ Neuroblastoma (schwannoma)
Sympathicoblast	→ Sympathicoblastoma
Neuroblast	→ Neuroblastoma
Sympathetic ganglion cell	→ Gangliocytoma
Primitive mesenchyme	
Fibroblast	→ Neurofibroma (Neurofibrosarcoma)

Neurofibromas. The origin of these tumors from one of the three nerve sheaths caused Verocay to suggest the term 'neurofibrosarcoma'. These tumors are thought to come from the perineural or endoneurial fibrous tissue and are distinguished from the tumors of the sheath of Schwann which are characterized by elongated fusiform cells with 'pallisading' of the nuclei. The two types of tumors are frequently confused. Heuer and Andrus (27) collected 20 authentic cases of intrathoracic neurofibroma and added 1 case. They also collected 19

cases of neurinoma (schwannoma) showing that the relative frequency is about equal. We can add 3 cases of neurofibroma and 1 case of schwannoma, all originating in the mediastinum.

CASE 24. J. A. V. This 33 year old white male complained of dull pains around his heart, associated with mild shortness of breath of 8 months duration. Five months after the onset of his complaint, chest roentgenogram showed a mass in the left mediastinum which seemed to be contiguous with the aortic outline. Fluoroscopy and electrocardiogram ruled out aortic aneurysm. Generalized lymphadenopathy developing 7 months after onset of his complaint complicated the picture, and the possibility of a lymphoblastoma was entertained. However, a biopsy showed reactive hyperplasia. Heterophile antibody agglutination was positive, and a diagnosis of mononucleosis, infectious, was confirmed. Following recovery from infectious mononucleosis, thorcotomy was performed which showed a tumor mass approximately 8 centimeters in diameter lying beneath the mediastinal pleura just above the superior aspect of the arch of the aorta. The left subclavian artery was stretched tightly over the tumor mass. The tumor was enucleated by blunt and sharp dissection and from gross appearances was completely removed. Recovery from surgery was uneventful. Pathological report was neurofibroma, benign, posterior mediastinum, left.

CASE 25. L. T. H. This 31 year old white male had a routine chest roentgenogram which showed a mass in the left posterior mediastinum. Except for a dry cough for a number of years, history was completely negative. Physical examination and laboratory studies were negative except for the roentgenogram which showed a dense rounded mediastinal tumor in the posterior mediastinum on the left, extending from the upper border of the sixth rib posteriorly to the lower border of the ninth rib posteriorly. Thorcotomy was performed and a tumor was removed from the posterior mediastinum on the left. Several pedicles which apparently represented nerve tissue extended into the intercostal spaces. These pedicles were clamped and ligated, and the tumor was removed. Recovery from operation was uneventful. Pathological studies showed an egg-shaped tumor mass 7.5 by 6 centimeters with a smooth, greyish yellow capsule. Microscopic section showed the tumor to be composed of fibrous tissue, nerve fibers, and xanthoma cells, but no true myxomatous tissue. Diagnosis: mesenchymal tumor including nervous and fibrous tissue and xanthoma cells, benign, predominantly neurofibroma.

CASE 26. D. L. This 22 year old white male was discharged from the Navy in November 1945. He was told he had a tumor in his chest and should have a recheck in 4 months. He later applied for work in a steel mill and the tumor was seen again on roentgenograms. He was advised to have it removed later.

duately. On admission to the hospital patient had no complaints. Physical examination was essentially negative. Laboratory studies were negative except for the roentgen ray examination which showed a left posterior mediastinal tumor arising from the region of the 6th thoracic foramen. There was a very slight calcification on the inferior margin of the 6th thoracic pedicle which suggested a dumbbell type of neurofibroma. Thoracotomy was performed and a solid mass in the left posterior mediastinum was easily removed. There was no pedicle extending to the 6th thoracic vertebra. Recovery from surgery was uneventful. Pathological report showed a spherical 4 centimeter mass with a smooth and glistening surface. Microscopic section showed the tumor capsule to be composed of coarse hyaline connective tissue and the tumor was composed of interlacing bundles of elongated eosinophilic cells with hyperchromatic nuclei. In many areas palisading was marked and fibers were delicately fibrillar. No evidence of malignant changes noted. Diagnosis: neurinoma (schwannoma) degenerating mediastinum, left.

CASE 37 F. R. B. This 31 year old white male was completely asymptomatic. Routine roentgenogram was read as showing a spot of the upper lung field on the right. Admission physical examination and routine laboratory studies were negative. Roentgenograms showed a lobulated mass in the superior mediastinum on the right. Bronchoscopy was negative. Thoracotomy revealed a firm tumor mass at the level of the second, third, and fourth ribs in the posterior mediastinum. It was removed by blunt and sharp dissection. Recovery from surgery was uneventful. Pathological report showed a reniform encapsulated mass weighing 62 grams measuring 8.2 by 3.8 by 3.3 centimeters enclosed by a thin fibrous capsule. One surface has three transverse poles dividing it into three almost equal lobules. The cut surface showed the smallest lobule to be greyish

translucent and uniform, the two larger lobules contained indefinitely outlined opaque orange yellow areas suggesting xanthomatous change rather than caseation. The rest of the tissue was greyish translucent. The middle lobule showed cystic degeneration and hemorrhage. Microscopic examination showed a fibrous capsule enclosing the tumor. In addition there was fat outside the capsule where the tumor was detached from its bed. Other sections showed thin pleura covering the capsule where it bulged into the pleural space. The tumor was composed of interlacing bundles of spindle nerve cells with some areas where palisading of nuclei was visible. Many engorged capillaries were present in the tumor. Many areas of edema with small cystic spaces were found. Other areas showed well marked cystic degeneration with hemorrhage in tissue around the small cysts. In one such area there were collections of closely approximated, hyalinized thick walled vessels suggestive of sclerosing anglioma. The opaque, orange, yellow areas seen grossly were areas of xanthomatous degeneration lying close to the capsule. The nuclei of the rather plump spindle tumor cells varied in size but mitosis was not seen. In the areas of cystic degeneration there was some round cell infiltration. Impression: This was a neurofibroma with areas suggesting neuroma with cystic degeneration some hemorrhage and xanthomatous degeneration. Diagnosis: neurofibroma, intrathoracic mediastinal, benign. (Figs. 40 to 43.)

Ganglioneuromas In 1932 Scott and Palmer reviewed the tumors of the peripheral sympathetic system and adopted a classification listing the tumors according to degree of differentiation. This was similar to the work done by Von Fischer in 1922. Ganglioneuroma lies with pheochromocytomas and astrocytomas in the completely differentiated group. There is

a very low tendency toward malignancy varying inversely with the age of the patient. Heuer and Andrus (27) collected 68 cases of intrathoracic ganglioneuromas including one of their own. Seventy four per cent of those cases with stated age were in children under 10 years. The prognosis is good if the tumor is surgically removable. We have 2 cases of this type to present.

CASE 18. A. P. T. This 22 year old white male first noted chest symptoms of dyspnea, dizziness, and pain in the left chest approximately 8 years previous to admission. He was sent overseas where he participated in combat duties with an infantry regiment. Because of chest symptoms, roentgenogram examination of the chest was performed and a diagnosis of tumor type undetermined was made. On admission his only complaints were dyspnea, mild, and intermittent mild pains in the left chest. Physical examination was completely negative except for dullness to percussion and absent breath sounds over the posterior left chest up to the level of the 5th rib. Roentgenogram examination showed a large sharply circumscribed opacity occupying the lower one third of the left lung field. There was no evidence of erosion of bone. Exploratory thoracotomy showed a large firm tumor mass occupying the posterior portion of the thoracic space. The tumor was densely adherent to the posterior chest wall at the level of the 5th to the 10th rib. It was lobulated and had a consistency of a neurofibroma or a ganglionic neuroma. It was entirely covered by pleura. The tumor was removed by blunt and sharp dissection and it was found to be originating in the posterior mediastinum on the left where a large branch of the aorta entered directly into the tumor mass. Recovery from the operation was uneventful. Pathological report showed a non malignant neoplasm—neuroma ganglionic, of left posterior mediastinum.

CASE 20. H. A. N. This 9 year old white male was completely asymptomatic. While he was undergoing routine examination for re-enlistment for the regular Army a roentgenogram was taken which showed a mass just to the right of the heart and seemed associated with the cardiac shadow. It was thought at that time that the patient had a cardiac condition. Cardiac studies were negative however and he was returned to active duty. Five months later he was admitted to a regional hospital because of frequent blackout episodes. These attacks came on rapidly and were explained by the patient as sudden "blacking out" during which time he would fall to the floor but would not lose consciousness. These episodes would last about 1 hour accompanied by generalized weakness. The attacks were followed by severe frontal headache lasting 5 to 6 hours. Chest roentgenograms taken at that admission showed the mass to be extracardiac in origin. He was transferred to this hospital for further treatment. Routine

laboratory examinations were within normal limits. Roentgenograms of the chest revealed a widening of the posterior mediastinum on the right back was very sharply outlined laterally. Fluoroscopic examination revealed no pulsation and no connection with the cardiac shadow. Examination of the esophagus by means of barium by mouth revealed no displacement or abnormality of the esophagus. The mass on the right had more of the appearance of an encapsulated pleural fluid pocket medially than that of a tumor mass. The complaints of "blackout periods" ceased and neurological clearance was given. Exploratory thoracotomy showed a large tumor mass in the posterior mediastinum extending into the posterior gutter of the right chest which was removed by blunt and sharp dissection. Postoperative course was uneventful. Pathological examination showed an oval encapsulated tumor weighing 200 grams and measuring 15 by 9.5 by 5.5 centimeters. The capsule was thin, permitting underlying pale, greyish yellow tumor tissue to be seen. A paper thin, smooth membrane covered the free surface and represented the stretched mediastinal pleura. The "attached" surface was rough, covered by a ragged sheet of fatty tissue extending from one pole to within 3.5 centimeters of the opposite pole and from one border to within 2 centimeters of the opposite border. Cut surface bulged and had a translucent appearance and slippery mucinous feel of myxomatous tissue. Cut surface consisted of indistinctly lobulated, translucent, rubbery dirty greyish, yellow tissue bulging as distinct nodules which occupied almost one half and extended into the opposite half for 6 to 3.5 centimeters. Between these firmer areas is more lumpy greyish, tan tissue. Fine white, fibrous streaks traversed the tumor. Vessels are not visible. There was no gross hemorrhage or necrosis. Microscopic section showed variation of tumor tissue in different areas. In some areas near the surface it was composed of definitely outlined, small nerve bundles separated by an edematous, fibrillar stroma. There was further tearing apart of the nerve bundle so that irregular bands of nerve fibrils irregularly arranged were scattered in the mucinous edematous stroma. Solitary ganglion cells and groups of ganglion cells were scattered here and there through the tumor and in some areas the tissue was quite suggestive of ganglion having been included in the tumor. Several fairly large nerves were buried in the tumor. The ganglion cells showed varying degrees of degeneration some had fenestrated borders, satellite cells were frequently seen surrounding the such granular cytoplasm of a ganglion cell in which a nucleus was seen. Only occasionally were definite ganglion cell nuclei recognizable. The loose fibrillar meshwork filled with edema fluid which supported the nerve bundles did not appear to be myxomatous tissue but was rather a mucinous degeneration of the stroma. Impression Ganglioneuroma arising apparently from the paravertebral ganglion showing extensive mucinous degeneration. It appeared benign and grossly was completely removed. Diagnosis

ganglioneuroma, paravertebral intrathoracic, posterior mediastinum, right benign. (Figs. 44 to 47.)

Neuroblastomas and neuroepitheliomas. These tumors are examples of the more malignant types of neoplasms derived from the nervous system. In the thorax they are most frequently seen in the mediastinum because of the concentration of sympathetic nervous elements in that area. Although malignant good results can be obtained by surgical removal when the tumor is localized.

PRIMARY TUMORS OF THE THYMUS

There is considerable confusion in the literature regarding classification of the tumors of the thymus. Pathologically the tumors fail to fall into well defined groups making classification a very controversial subject. Indeed the reports of the tumors sometimes fall into groups according to nationality. Ewing states:

It is significant that the carcinomas have been recorded almost entirely by French observers, while practically all the German reports are of sarcoma. The authors cannot alleviate the confused situation we are mentioning these tumors merely to be considered in differential diagnosis.

Benign thymomas. The present knowledge of the relationship between myasthenia gravis and tumors of the thymus is sketchy. Following the work of Blalock, the surgical approach to the treatment of the disease has been attempted in some cases but the results have been far from conclusive. Viets reported the cases of 15 surgically treated patients; 4 showed thymomas, 3 showed thymus hyper-

plasia, and the rest were normal thymuses. One of the patients with a normal thymus had complete remission of the symptoms of myasthenia gravis. Of the 4 with thymomas there was no indication that they were more improved than those with hyperplasia or those whose thymus was normal. Since neostigmine has been so successful in the treatment of most cases of myasthenia gravis it is well to take the conservative view and defer surgery except in those patients who show an enlarged thymic shadow on x-ray examination. We have one case of thymus hyperplasia which showed improvement following thymectomy.

CASE 30. H. H. W. This 58 year old Japanese male had been complaining of diplopia, bilateral ptosis, weakness of the jaw on biting and hoarseness and vocal fatigue, increasing in severity during the previous 10 months. Three months previous to admission he was examined at another hospital where the diagnosis of myasthenia gravis was confirmed when the patient improved on prostigmine bromide therapy which was given every 2 hours in alternating doses of 30 milligrams and 15 milligram. He also received $\frac{3}{4}$ of a grain of ephedrine sulfate three times daily. On this therapy all of his symptoms improved except the diplopia. He was transferred to this hospital for thymectomy. On admission here physical examination showed a moist skin, pupils reacted normally to light and accommodation. There was a marked ptosis on the left and moderate ptosis on the right. There was an apparent slight internal strabismus. There was some weakness of the neck muscles and some weakness of the muscles of the upper extremities more pronounced on the right in the extensor groups. All other findings were within normal limits. Laboratory examination was within normal limits except for the white count which showed 21,000 white cells with 86 per cent polymorphonuclears. Roentgen ray examination on

admission was negative. Previous to surgery the prostigmine therapy was discontinued for 3 to 4 days then the patient was given 10 grains of quinine orally in the morning and at noon. During the afternoon, he complained of marked weakness of his neck muscles of such proportions that he could not raise his head from the bed. There was also an increase in the ptosis, more marked on the left. Fluoroscopy was performed with a barium swallow showing diminished swallowing time which promptly returned to normal following $1\frac{1}{4}$ milligrams of prostigmine intramuscularly with improvement of the ptosis and the diplopia. Following this diagnostic test the thymus was removed through a sternum splitting incision from which the patient recovered uneventfully. The pathological report showed an irregularly shaped thymus gland weighing 65 grams with an overall length of 18½ centimeters. Microscopic section showed a diffuse hyperplasia of both cortex and medulla. The cortical endothelial cells were prominent, and the medulla epithelial elements were hyperplastic with unusually large thymic corpuscles. No malignant changes were noted. Diagnosis: thymic hyperplasia benign. Postoperatively there was marked improvement of all the symptoms of myasthenia gravis but patient continued to have moderate generalized weakness and diplopia. It was found that a single dose of prostigmine 0.5 milligram, given intramuscularly before arising, gave him marked improvement in the diplopia and the generalized weakness. Patient was discharged 4 months after thymectomy his general condition markedly improved (Figs 48 to 51).

Malignant thymomas These tumors have been classified by Ewing as falling into two groups (1) lymphosarcoma or thymoma (2) carcinoma. He adds a third group called spindle-cell or myxosarcoma, which is very rare. The first group (lymphosarcoma) he considers as originating from reticulum cells with the lymphocytes being largely passive. This is the most common type. These tumors may be encapsulated within the mediastinum or may assume invasive properties and metastasize to distant sites. Surgery should be attempted in every case even if only for biopsy if the lesion appears localized. X-ray therapy in inoperable cases has been reported as useless but should be attempted in all cases because of the frequent pathological confusion with more radiosensitive tumors. We have one case of thymic carcinoma which has responded remarkably to deep x-ray therapy but the follow up is too short to evaluate the case at present (12 months after surgery was carried out).

CASE 31 R. C. W. This 30 year old male only had a tumor of the right anterior mediastinum discovered on routine chest roentgen-ray examination at a separation center. The patient had no cardiorespiratory symptoms except for asthma which he has had since the age of 5 and which has been much improved during the past 3 years. Physical examination was essentially negative except for decreased breath sounds, decrease in vocal fremitus, and a few rales to the right of the sternum between the third and fifth intercostal spaces. Laboratory studies were within normal limits with the exception of chest roentgenograms which showed a large anterior mediastinal mass measuring approximately 12 by 14½ centimeters in diameter. There appeared to be beads of calcification along the wall along the right inferior border of the mass and the impression was an anterior mediastinal tumor probably teratoma. A sternum splitting incision was made, mediastinotomy was performed, and a large firm tumor mass was found in the anterior mediastinum. This mass was freed up along the left border, but in several places along the posterior aspect of the tumor it had invaded the pericardium and was densely adherent to the underlying great vessels. Exploration of the vena cava and the bronchial veins showed that the tumor was apparently invading the lumen of the vessels. A section of the tumor was taken for frozen section, and the report was malignant thymoma. The mediastinum was closed, and the patient returned to the ward in good condition. Postoperatively the patient received 1500 roentgen units through each of four portals, anteriorly and posteriorly, and 1000 units through each of two portals laterally. At the termination of the x-ray therapy the mass had reduced remarkably in size so that it could barely be seen by x-ray and fluoroscopy. Repeat x-ray films were taken 5 weeks following x-ray treatment, and there was no evidence whatsoever of an anterior mediastinal tumor. Follow up at the end of 1 year shows the patient still asymptomatic, and roentgenograms are negative. The pathological report showed large cells with abundant acidophilic cytoplasm. Nuclei varied markedly in size and shape, but in general were round to oval with distinct nuclear membrane, and somewhat vesicular nucleus. Mitotic figures were occasionally seen. Cells were arranged in small groups separated by narrow strips of hyaline tissue forming a definite trabecular outline. Diagnosis: carcinoma, thymic. (Figs. 52 to 55)

Thymic cyst Cystic disease of the thymus is an extremely rare entity in adults. A few cases are reported in infants most of them are believed to be secondary to congenital syphilis. Ribbert believed that the thymus consists of a series of epithelial channels, their development being arrested by syphilis which caused the "Dubois abscess" or cyst formation. Chlan agreed with Ribbert's theory but felt

Fig. 56

Fig. 57

Fig. 58

Fig. 56 Preoperative roentgenogram. Case 32
Fig. 57 Gross specimen intact

Fig. 58 Gross specimen opened
Fig. 59 Showing thymic tissue and cyst wall

that syphilis was not the only etiologic factor.

Previous descriptions of thymic cysts in adults have been limited to small lesions found at autopsy. One case presented by Kopac (also an autopsy specimen) described a left thymus lobe entirely replaced by a cluster of grape-like cysts. This specimen is similar to our case except his cysts were separate from one another and involved only one lobe of the gland. Kopac summarized the morphogenesis as follows: The first step in cyst formation is the degeneration and necrosis of the parenchyma in the medullary substance. There is a much greater deterioration of the blood vessels than the degree of involution of the thymus could explain. In these necrotic spaces fluid accumulation takes place. The surrounding reticulum cell assumes a flattened appearance and form an epithelial layer through which the entire picture assumes appearance of a cyst wall. The cyst increases at the expense of the surrounding parenchyma. As the Strandberg layer is reached by the cyst the cyst acquires a connective tissue wall. The parenchyma which surrounds the cystic cavities is formed by the cortical substance.

We are presenting a thymic cyst in an adult which completely replaces the gland; is not due to syphilis; and is apparently the first cyst of its type and size to be successfully removed.

CASE 32 T. C. A. Jr. This 22-year-old white male was admitted to this hospital for minor lumbago of his right shoulder and chest. Physical examination was essentially negative except for the minor hurns which were treated and healed uneventfully. Routine roentgenogram of the chest showed a well-defined of the superior mediastinum. Comparison with roentgenograms taken 3 months previously showed that the mass was present at that time although much smaller. Bronchoscopy was negative. Further roentgenographic studies showed a lobulated mass in the anterior mediastinum. Thoracotomy was performed through a posterolateral incision and a multiloculated anterior mediastinal cyst was removed. Postoperative course was uneventful. Pathological report showed an inverted V-shaped multicystic tumor weighing 74 grams without fluid content. Filled with 150 cubic centimeters of water, it weighed 240 gram. The specimen was bilobed, one lobe measuring 14 by 2 1/2 by 5 centimeters and the other lobe measuring 12 by 5 by 7 1/2 centimeters. Microscopic sections showed that this was definitely a polycystic and multicystic thymus. Abundant thymic lobules were still visible in various portions of the walls of the cystic lobes. In the thymic tissue Hassall's corpuscles were seen with occasional giant cell and xanthoma cell present. There appeared to be a periphery of the epithelial ramifying transitional thymus. Cystic degeneration occurred in these. Diagnosis: polycystic thymus (Figs. 56 to 59).

PRIMARY TUMORS OF LYMPH NODES

The only characteristic feature of this group of tumors is that they frequently involve only a single group of nodes in the early stages. This fact is important in a discussion of medi-

Fig. 60. Preoperative roentgenogram. Case 33.

Fig. 61. Gross specimen.

Fig. 62. Showing Reed-cell and marked fibrous thick-

is replacing the lymphoid and plasma cell elements.

Fig. 63. Postoperative and post-radiation roentgenogram.

astinal tumors because that may be the only site where the disease is found. If the disease is generalized, peripheral node biopsy may establish the diagnosis. When mediastinal nodes are the only positive findings, we believe it imperative that mediastinal biopsy be performed not for medical curiosity, but for aid in planning intelligent therapy and to ascertain prognosis. The mortality of mediastinal exploration is no greater than that of abdominal exploration (44) and some of us believe that morbidity is even less.

Lymphosarcomas. Ewing classifies lymphosarcomas into two groups: (1) reticulum cell sarcoma, (2) malignant lymphocytoma. Although histologically different, the two types are considered as one for clinical purposes. Lymphosarcoma is most often found in a definite chain of lymph nodes and from there becomes a generalized disease. Primary sites, in order of frequency, are cervical, mediastinal, retroperitoneal and mesenteric nodes. In the mediastinal type the bronchial nodes may be involved with extensions to pericardium or pleura or lung with marked pulmonary symptoms (Ewing). Extirpation may be hazardous, but at least the attempt should be made because the results from x-ray therapy have been palliative at best. Even with surgical removal, recurrence is the rule.

Hodgkin's disease. In their excellent monograph on this subject, Jackson and Parker showed mediastinal or hilar nodes to be involved in 52 per cent of their 174 cases of Hodgkin's granuloma, with one third of the

cases of Hodgkin's sarcoma showing involvement. It is to be noted that in their 90 cases of granuloma and 10 cases of sarcoma, only 1 case showed mediastinal involvement, with no peripheral lesions. This point is emphasized because in the past a favorite objection to mediastinal exploration was that the lesion may be Hodgkin's. We have treated 15 patients with Hodgkin's during the past year, all with pathologic diagnoses, and in only 2 was it necessary to resort to mediastinal biopsy. One abstract follows:

CASE 33 C. L. B. This 20-year-old white male had complaints of weight loss and malaise 6 months previous to admission. At the onset of his complaints, biopsy had been taken from a palpable node in the right inguinal region, and the pathological report was negative. Roentgenograms of the chest at onset of complaints showed an enlargement of the mediastinum, type undetermined. At time of admission to this hospital, complaints were minimal. Physical examination was negative. Laboratory studies were within normal limits with the exception of the roentgenogram which showed a diffuse enlargement of the superior mediastinum. Test doses of x-ray therapy showed response to the treatment, and a full course of deep x-ray was given to the mediastinum. Patient was discharged and returned in 3 months, at which time a palpable node was found in the left axilla. Biopsy of this node was performed and a pathological report again was negative. He was discharged again for 30 days, and on return the x-ray films of the chest showed nodular widening of the mediastinum on the left at the level of the first rib anteriorly and also just superior to the left hilum with increase in size in the past 5 months. Mediastinal exploration, as performed with uneventful recovery. Pathological diagnosis: Hodgkin's disease, lymphogranuloma type, mediastinal node left (Figs. 60-63).

Fig. 67. Postoperative roentgenogram.

Boeck's sarcoid The mediastinal manifestations of this little known disease frequently simulate the tumors already discussed. Boeck's sarcoid is a pitfall in the common practice of using a test dose of deep x-ray therapy to establish the diagnosis of malignant lymphoma. Riesner (1944) states that over 85 per cent of 35 cases showed mediastinal node involvement and that 6 of these cases showed practically complete disappearance of the shadows while being watched; half of the total showed some regression. Certainly a test dose of x-ray during this regression period would lead to an erroneous diagnosis of lymphoma.

We have 4 cases to present—all were seen in a recent 6 week period. All had extensive medical work up and were referred to the Tumor Service as mediastinal tumor type undetermined. Each one shows a specific point of interest. The first 2 had mediastinal involvement with no palpable peripheral nodes; the third had only one peripheral node found deep in the cervical triangle after repeated careful examinations over a 3 month period (he also had uveoparotid involvement—Mikulicz's disease—since early childhood) and the fourth showing regression of mediastinal involvement to normal over a 5 month period. All cases were proved by biopsy: the first 2 by mediastinal nodes; the second 2 by peripheral nodes.

CASE 34. E. K. C. This 24 year old white male was admitted with a diagnosis of Hodgkin's disease.

He had slight chest pain on the left with occasional cough and a weight loss of 20 pounds in 9 months. Physical examination was essentially negative. Laboratory studies were within normal limits. Exploratory thoracotomy showed multiple nodes in the mediastinum and a biopsy showed Boeck's sarcoid. Recovery from surgery was uneventful. (Figs 64 to 67.)

CASE 35. D. C. R. This 19 year old colored male was admitted to this hospital with a diagnosis of Hodgkin's disease. A routine roentgenogram disclosed mediastinal masses and a diagnosis was made without biopsy. Physical examination on admission was negative. Laboratory studies were within normal limits with the exception of roentgenograms which showed moderate, bilateral hilar and superior right mediastinal adenopathy consistent with lymphoblastoma. Exploratory thoracotomy revealed multiple mediastinal masses and biopsy was made. Recovery from the operation was uneventful except for moderate superficial infection of the wound which responded to conservative therapy. Pathological diagnosis was reported as sarcoid (Boeck's) generalized.

CASE 36. F. A. N. This 27 year old colored male had intermittent dull pain in his right chest with cough and slight amounts of mucopurulent sputum of 1 year's duration. There was a weight loss from 150 pounds to 106 pounds. Roentgenogram of the chest showed a 2 by 5 centimeter mass lying just to the right of the tracheal shadow just above the right main bronchus. There was no evidence of pulsation, and it did not encroach on the esophagus. Physical examination was negative except for a single palpable lymph node in the left axilla. Laboratory studies were negative. Biopsy of the left axillary node showed sarcoidosis, lymph node axillary left.

CASE 37. J. L. This 25 year old colored male had a nonproductive cough, fatigue, hoarseness, and pain in the left anterior chest of 4 months duration. He was admitted to this hospital with a diagnosis of lymphoma malignant of mediastinum. Physical

examination was essentially negative with the exception of a single palpable node in a deep cervical chain on the right and enlargement of the uveoparotid glands, bilaterally. Laboratory studies were within normal limits. Biopsy of the cervical node showed sarcoid lymph node neck right.

Endotheliomas This is a rare type of primary tumor of the lymph nodes affecting either one node or a group of nodes but usually progressing to a systemic type of disease. Even when locally removable, it is a recurring malignant tumor. Histologically it is confused with secondary carcinoma.

PRIMARY AND SECONDARY SARCOMAS

The connective tissue tumors and the neurogenic tumors already mentioned may degenerate to form primary mediastinal sarcomas notably the fibromas, xanthomas, chondromas, and neurofibromas. Any of the connective tissue in the mediastinum may be the site of sarcomatous growth. Unfortunately there is no way to distinguish between the benign mediastinal tumors and the malignant on x-ray examination. Total removal is possible in early cases and metastasis is usually late.

Secondary sarcomas of the mediastinum are extremely rare as hematogenous spread is more frequent therefore involving the lungs before the mediastinum.

PRIMARY AND SECONDARY CARCINOMAS

The most frequent origin of primary carcinoma of the mediastinum is the thymus although many times the primary site cannot be determined due to the extent of the lesion. Primary sarcomas are three to four times as frequent as primary carcinomas. Surgical intervention offers no hope as the lesion is asymptomatic in the early stages and the mediastinal contents are extensively involved by the time exploration is sought. X-ray therapy is palliative in a few cases but the most effective treatment is section of sensory nerve roots to allay pain.

Secondary carcinomas of the mediastinum usually come from lung, esophagus, or breast and occasionally from abdominal viscera. Treatment is purely palliative.

CASE 38. V. L. G. This 39 year old white male had recurrent episodes of pain between the shoulder

blades of 4 months duration. The pain was deep seated, and continuous, being relieved only by leaning up against something. Examination revealed a cyanotic dyspneic, well developed, young male. Thorax was symmetrical and expansion unequal. There was supraclavicular and infraclavicular retraction on inspiration. There were real varicosities over the anterior chest. Resonance was impaired at the right base, and breath sounds were diminished in both bases. There were healed blow wounds in both axillae. The rest of the physical examination was negative. Roentgenograms of the chest revealed a marked widening of the mediastinal shadow with some evidence of mild atelectatic changes in the lower lobe on the left. Patient received a diagnostic test dose of x-ray therapy over the mediastinum with no evidence of regression of the tumor mass. An anterior mediastinotomy was performed which showed a large tumor mass in the anterior mediastinum which could not be removed. Biopsy was taken. Recovery from the operation was uneventful but the patient continued to lose weight and strength in spite of heavy doses of x-ray therapy over the mediastinum. His course was progressively downhill, and he expired 38 days following surgery. Pathological report: carcinoma, anaplastic, mediastinum.

CASE 39. W. A. H. This 38 year old, late male had a routine chest roentgenogram 6 months previous to admission which was said to be negative. One month later a second routine chest plate was taken and a small tumor mass was found to the right of the midline in the mediastinum. Comparison with the previous film showed a small mass present at that time. During the subsequent 5 months, he was carefully observed with repeated roentgenograms which showed progressive enlargement of the tumor mass. After the fourth month a trial dose of x-ray therapy was given which was reported as being inconclusive. The patient was transferred to this hospital 6 months after his first roentgenogram in markedly poor condition. He was complaining of mild pain in the right chest, marked weakness, and dyspnea. Physical examination showed marked weight loss and complete dullness to percussion over the entire anterior right chest extending into the axilla and into the right base posteriorly. There was complete absence of breath sounds in this area. There were a few breath sounds coming through over the right chest posteriorly at the apex. Left lung was negative to physical examination. Laboratory studies were within normal limits except for a red count of 4,000,000 and a hemoglobin of 75 per cent and the roentgen studies which showed a fairly well delineated mass in the right hemithorax apparently originating in the anterior mediastinum and extending laterally resulting in a compression of the right lung and shift of the heart shadow toward the left. Review of the old films showed a 5 millimeter mediastinal mass barely projecting into the right hemithorax present 6 months previous to admission. The x-ray diagnosis was a mass of malignant nature, and from its location thymic origin was considered.

Fig. 71. Autopsy specimen showing extent of pulmonary infiltration.

Fig. 71.

Exploratory thoracotomy was performed and an extremely large mass was seen markedly adherent to the right lung and compressing it posteriorly. The mass was entered and found to consist of a moderately thick cyst wall with a tremendous amount of organized hematoma in the center. The hematoma was evacuated from the mass and no bleeding points were found. A section of the wall was taken for biopsy. Thorax was closed, and the patient was returned to the ward in poor condition. Pathological report showed a papillary carcinoma. However, there was a suggestion of endothelial origin, original site undetermined. Patient required numerous thoracenteses to remove the large collection of fluid formed postoperatively. The reaction from x ray therapy was too severe, so that he received only a few hundred roentgen units over the anterior mediastinum. Death occurred 2 months after surgery (Figs 68 to 71).

CASE 40 P T. This 51 year old colored male had a persistent cough of 13 years duration. Ten years previous to admission he expectorated blood for 1 week. He had recurrence again 2 years previous to admission, and 1 year previous to admission, each attack lasting for about 1 week. Four months pre-

vious to admission, he had marked weight loss, malaise, and left chest pain, so he was seen by a physician who took chest roentgenograms and told him he had no trouble, so he returned to work. His disabilities continued to grow more severe. Finally a second roentgenogram was taken 4 months after the onset of acute symptoms and he was referred to this hospital with a diagnosis of mediastinal tumor, type undetermined. Physical examination was essentially negative except for moderate weight loss. Laboratory studies were within normal limits except for the roentgenogram of the chest which showed moderate nodular mediastinal enlargement. Thoracotomy was performed with removal of a mediastinal lymph node for biopsy. Recovery from thoracotomy was uneventful. Pathological report on the biopsy revealed anaplastic carcinoma, original site undetermined. Postoperatively he received 1400 roentgen units to each of four portals, two anteriorly and two posteriorly with complete remission of symptoms. He was discharged for 1 month at which time a second course of x ray therapy was given, bringing the total roentgen units to 2150 over each of the four portals. On his third admission 1 month after discontinuance of the second course of treatment he was given a

third course which consisted of 2,400 roentgen units over each of two lateral portals. Until this time the patient had been feeling well—at least holding his own except for a single episode of pain directly in the wound, and on palpation a single nodule was found lying in the skin. This nodule was removed local anesthesia being used and the pathological report showed anaplastic carcinoma the same type that was removed from the mediastinum. Apparently there had been seeding of the carcinoma into the skin at the time of the original biopsy. Recovery from this minor surgery was uneventful with no recurrence in the wound. Following the third course of x ray therapy patient gradually began to fail, complaining of pain over his left chest and left shoulder. He had marked weight loss, and roentgenograms showed a diffuse density in the lower two-thirds of the left lung field. The patient expired 7 months after mediastinal biopsy. Autopsy showed the carcinoma still confined to the mediastinum with postirradiation fibrosis and bronchopneumonia at the base of both lungs.

INTRATHORACIC GOITERS

This group of mediastinal tumors is mentioned merely for differential diagnostic purposes. Several goiters in the mediastinum with no connection with the thyroid have been reported. Mason's was located in the posterior mediastinum and was successfully removed by extrapleural mediastinotomy. We have 1 case of mediastinal goiter with no connection with the thyroid. It was located between the bifurcation of the trachea and the base of the heart extending laterally into the right thorax.

History was completely negative. Physical examination was within normal limits. Laboratory studies were negative except for roentgenograms which showed an ovoid 6 centimeter mass, lying attached to the pericardium in the region of the junction of the right ventricle and right atrium. The x ray diagnosis was probable pericardial cyst. Thoracotomy was performed and the mediastinal mass was removed. It was lying anterior to the pericardium, and extending upward in the mediastinum to the bifurcation of the trachea. Recovery from operation was uneventful. Pathological report showed a roughly spherical mass measuring 5.5 centimeters in diameter with an attached mass measuring 5 by 3½ centimeters in diameter. On cutting the specimen, considerable turbid old blood exuded under pressure. The large space was filled with friable yellowish-gray fibrin. Attached tumor structure was multiloculated and contained clear straw colored fluid. The tumor was composed of glaucous gray tissue. On section of the cyst wall, there was an area of thymic tissue closely associated with fibrous capsule. Extending over the thymic tissue and extending into the cyst was an adenomatous structure with very small rosette-like tubule, and as the cavity of the cyst was approached, these tubules became larger forming increasingly larger follicle-containing colloid material. Cells were regular in size and shape with large round nuclei with finely distributed chromatin. The cytoplasm was poorly discerned, but granular and appeared to have a secretory function. No mitotic figures were noted or evidence of manifest malignant change. The tumor was considered to be a benign aberrant thyroid tissue having no connection with the normal thyroid gland and lying completely within the anterior mediastinum (Figs. 72-75).

SUMMARY

CASE 41. I. O. S. This 24 year old white female had a routine chest roentgenogram which showed a

1. A classification of mediastinal tumors is presented

2 The various types of tumors are discussed under separate headings.

3 Emphasis is placed on the importance of thoracotomy for pathological diagnosis with extirpation of the mass if it is operable. Evidence is presented to show that thoracotomy is a safe rational procedure with no mortality in properly selected cases.

4 Thirty five mediastinal cysts and tumors are presented with six additional cases of differential diagnostic conditions

A TECHNIQUE FOR PORTACAVAL ANASTOMOSIS (ECK FISTULA)

C. STUART WELCH, M.D. Boston, Massachusetts

THE recent reports of Whipple and of Blakemore and Lord (2) of their experiences in the treatment of patients with portal system hypertension by means of venous shunt operations have created renewed interest in a type of surgery which should be given a trial in these patients whose lives are constantly threatened by massive hemorrhages from the gastrointestinal tract. Whipple's lucid article and Blakemore's (1) subsequent report of the results in 25 operations point out the problem, the indications for these operations, and the results that have been obtained to date by the group working at the Presbyterian Hospital. Knowledge of this subject has come largely from these workers.

Two operations splenic renal vein anastomosis and portal vein inferior vena cava anastomosis, have proved most useful in decompressing the portal system. When portal hypertension exists, pressure readings in this system are frequently 3 to 5 times greater than normal. Everyone is familiar with the routes of collateral circulation which develop naturally by the enlarging of normally small venous communications in an attempt to circumvent portal venous obstruction. Esophageal varices frequently develop and it is the rupture of such varices that produces alarming hemorrhage. In addition to this hemorrhage factor ascites may develop in part at least on the basis of portal hypertension although the state of liver function is probably a more important factor in most cases of liver cirrhosis. It can be easily seen that a successful anastomosis of a portal system in which the pressure is in the neighborhood of 400 millimeters of water to a systemic venous system whose pressure may range from 40 to 80 millimeters of water should greatly relieve the hazard of these two complications of portal hypertension. Whether

spleno-renal anastomosis or portacaval anastomosis should be used in a given instance depends upon the site of obstruction. In general when both can be used as is true in the intrahepatic bed block of liver cirrhosis, the larger portacaval shunt is to be preferred.

While my own experience with Eck fistula operations is limited, in this communication I wish to describe a method of portacaval shunt which I have used in a patient whose case report follows. The technique to be described avoids complete caval obstruction and is technically not too difficult. Blalock (3) has said that it is not necessary to occlude the vena cava completely during this operation but has not described the method he uses. An early operation in 1913 reported by Rosenstam was performed as a side to-side anastomosis with intermittent caval occlusion. Complete caval obstruction was the complicating factor in other early operations (5).

An end-to-side anastomosis of the portal vein to the inferior vena cava was performed above the renal veins and the anatomical result may be seen in Figure 1a. Dissection of the hepatic pedicle and the isolation of the portal vein is time consuming. The essentially important features of this anastomosis are two. In Figure 1b it can be seen that the vena cava is never completely obstructed a free flow of caval blood can pass beneath the clamp which has temporarily isolated a portion of the wide cava. The clamp used is the ordinary Thomas Smith intestinal forcep which has been used for years in the operation of anterior resection of the rectum. It has spring blades and does not injure the tissue. For emergency use, loops of umbilical tape are placed above and below the clamp. The second feature of the anastomosis is the method of suture. The evertting suture described by Blalock (4) has been employed in a medial and lateral row as shown in Figure 1c. After completion of the anastomosis and removal of

From the Department of Surgery, Tufts College Medical School and the Carney Hospital, Boston, Massachusetts

Fig. 1. a, Completed suture portacaval anastomosis. b, Anastomosis of the end of the portal vein to the side of the vena cava above the renal vein entrances with the Thomas Smith clamp in place. Note free caval flow beneath the clamp. c, Anastomosis completed. Note everted type of suture.

the clamp one small leak was found which was controlled with one interrupted suture. Three zero Deknatel suture was used.

This method of anastomosis has the advantage of not obstructing the vena cava. It can therefore be done almost at leisure. The Blakemore method of nonsuture anastomosis with a vitallium cup which is placed on the end of the portal vein and later secured into the side of the cava by pursestring sutures requires that the cava be obstructed during this maneuver. Complete obstruction of the inferior vena cava, so well tolerated below the renals, can only be borne with safety above the renal veins for an estimated 10 minute period. Longer obstruction incurs serious kidney damage with resulting anuria. On one

occasion I have shut off the vena cava for too long a time in order to repair a rent in this vessel caused by attempting to pursestring a vitallium tubed portal vein. Death with anuria resulted 5 days after operation. This important time factor in methods which require caval obstruction can be avoided by the method described. Another advantage of this suture method is in its preservation of the full length of the portal vein after its severance close to the liver. Cuffing of the vein over a vitallium tube loses a valuable half inch of this vessel.

The theoretical disadvantage of suture anastomosis is concerned with intravascular clotting at the anastomosis with exposed sutures as the precipitating factor. The non

suture anastomosis is supposed to avoid this contingency. The pressure differential however between the portal system and the vena cava should avoid this complication since there is effected a shunt lesser but similar to an arteriovenous communication. These latter fistulas are in the normal course of events very liable to keep open.

It is quite probable that the clamp method of anastomosis described cannot be applied in all cases. When it can however it will be found I believe to be technically less difficult and less dangerous. The Blakemore tube method on the other hand has been found to be very satisfactory for the group working with this method who have developed great skill in the technique. This type of suture technique, I present as an alternative method

CASE REPORT

Portacaval anastomosis for portal hypertension caused by intrahepatic portal bed block (cirrhosis of the liver)

H.L., a young man 24 years of age was referred by Dr. William Moloney who had attended him for some time for severe gastrointestinal hemorrhages from oesophageal varices, the result of hepatic cirrhosis.

In April of 1944 while in the service, this patient began to complain of weakness, dizziness, and lassitude with occasional fainting spells. These may be interpreted as probably the result of an anemia. On one occasion he fell off a gun emplacement and was hospitalized with a questionable diagnosis of head injury. In November of 1944, while an Army Hospital patient, he had his first severe gastrointestinal hemorrhage. There was a large loss of blood requiring several transfusions. A diagnosis of splenomegaly with Banti's syndrome was made and in April, 1945 a splenectomy was performed at the Cushing General Hospital. The patient was subsequently discharged from the service on certificate of disability. In December of 1945 about 8 months after splenectomy he was admitted to the Carney Hospital with another exsanguinating hemorrhage. This

episode was treated by transfusions of blood. Two other hemorrhages occurred before his admission in January of 1945 for study and operation.

On this admission he was found to be in good general health. Physical examination revealed only a slight enlargement of the liver and a healed left abdominal splenectomy wound. There was a mild anemia, the red blood count numbered 3,400,000 per cubic millimeter of blood and the hemoglobin value was 75 per cent. White blood count was 9,100 with a normal differential count. Liver function tests showed good function. Total protein measured 6.7 grams per 100 cubic centimeters of serum with 4.0 grams of albumin and 2.7 of globulin. There was a 15 per cent retention of bromsulphalein in 3/4 hour with 10 per cent in 1 hour. Cephalin flocculation test was reported as 2+ the total cholesterol value was 160 milligrams per cent, cholesterol ester 100 milligrams, free cholesterol 60 milligrams. The boric acid excretion test was reported as 4.3 grams of benzoic acid excreted in 4 hours. On roentgenologic examination the esophagus was widened and there were well marked varices. A diagnosis of intrahepatic portal bed block with hypertension was made.

On January 27 a portacaval anastomosis was made according to the method described. Cirrhosis of the liver was found and a liver biopsy secured. Portal vein pressure measured 400 milligrams of water at operation. The patient was hospitalized for 4 days. Postoperative complications included right lower lobe atelectasis, a wound hematoma, and an episode of partial intestinal obstruction, none of which were alarmingly serious.

Since operation the patient has remained well and his liver function is being followed. It remains for time to elapse before an estimation can be made of the value of the operation in his case. Absence of hemorrhages in the future will be practical evidence of successful reduction of portal hypertension.

TUMORS OF THE ISLETS OF LANGERHANS

RODOLFO LOPEZ-KRUGER, M D and MALCOLM B DOCKERTY M D

Rochester Minnesota

LANGERHANS in 1869 first described the pancreatic "islets" which now bear his name and Nicholls in 1902 observed an adenoma arising from these structures. Nevertheless it was the discovery of insulin (4) and its production by certain of the islet cells which led investigators to wonder about hypoglycemia resulting from hyperinsulinism with its possible relationship to islet cell hyperplasia. In 1924 Harris suggested that an excess of insulin in the blood might be brought about by the presence of a hyperfunctioning tumor of pancreatic islet cells. Three years later his prediction was fulfilled when Wilder and co-workers recorded the first instance of such a tumor. Even though their tumor was a carcinoma with hepatic metastasis a finding in itself unusual they were able to demonstrate by biochemical means that the cells although undifferentiated elaborated insulin in large amounts. Since 1927 an increasing number of publications dealing with benign and malignant neoplasia of this type has evidenced a lively interest in the subject. The past 15 years have witnessed in this regard the development of many refinements of clinical and laboratory diagnosis. Surgeons through accumulated experiences have learned how and where to search for islet cell tumors, which are frequently small and often multiple. Pathologists have contributed their share of knowledge in the matter of employing special stains (22-24) which have unveiled the important rôle of the so called beta cells in the production of insulin by normal and neoplastic islet cells. They have failed however to help their clinical colleagues in the problem of establishing microscopic criteria of 'malignancy' in functioning pancreatic tumors.

Feeling that in the case of such a rare lesion the analysis of a large series might shed some light on the malignant potentialities of islet cell neoplasms we undertook comprehensive study of the problem with our prime interest centered on the histopathologic aspects.

MATERIALS AND METHODS

In the 20 years preceding September 1945 there have been observed at the Mayo Clinic 38 patients who presented the syndrome of spontaneous hypoglycemia on the basis of pancreatic islet cell tumors confirmed at operation or at necropsy. This group of cases constituted the nucleus for the present report.

With the aim of ascertaining the incidence of islet cell tumors the records of 10,314 consecutive necropsies from the Section on Pathologic Anatomy were studied. These records revealed a total of 44 tumors which had been discovered by routine methods of examining the pancreas. Eight of these tumors were functioning and accordingly are listed in the aforementioned group.

For the third phase of our study we are indebted to Dr. Pease of the Section on Pathologic Anatomy who furnished us with the results of her careful review of 500 consecutive pancreases studied at necropsy. The material from two pea sized and six microscopic adenomas was thus added to our series in a demonstration of what actually approximates the incidence of these tumors.

With a view to studying the relative number the limits of size and the staining properties of islet cells a number of pancreases were secured at the necropsy table and blocks were taken from various portions. This part of the study was especially helpful in the interpretation of the results of special staining methods outlined in later paragraphs.

From all of these tissues single or multiple blocks were selected so as to include when possible the junction of normal and neoplastic material. When the specimen was surgical

Abridgment of thesis submitted by Dr. Lopez Kruger to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M. S. in Medicine.

From the Department of Medicine, Mayo Foundation, and the Section on Surgical Pathology, Mayo Clinic.

and fresh, portions were placed in 10 per cent formalin and in Bouin's fluid the former being suitable for routine hematoxylin and eosin stain and the latter for the chromium hematoxylin phloxine stain as recommended by Gomori (22). Older specimens had been fixed in formalin. Blocks cut from these were placed in bottles containing fresh formalin and studied from Mallory, Heidenhain stain preparations. In a few cases in which a stain was desired to demarcate clearly acinar from islet tissue the phosphotungstic acid hematoxylin staining method of Mallory was employed.

CLASSIFICATION

From a careful review of the literature correlated with a study of our slides of pathologic tissue and a subsequent appraisal of the clinical records of our cases it became apparent that the tumors could be divided conveniently into the following groups: (1) adenomas of islet cells without hypoglycemia; (2) adenomas of islet cells with hyperinsulinism; (3) metastasizing carcinomas of islet cells without hypoglycemia; (4) metastasizing carcinomas of islet cells with hyperinsulinism; (5) borderline malignant islet cell tumors with or without hyperinsulinism. Subsequent paragraphs will deal with the clinical and pathologic aspects of these individual groups and include followup studies on the surgical cases up to but not including September 1945. However as a prelude to presenting the rather complex histopathologic aspects of the tumors we find it convenient at this point to review briefly our present knowledge of the normal histologic characteristics of the pancreatic islets of Langerhans particularly as elucidated by the use of newer methods of staining.

HISTOCYTOLOGIC ASPECTS OF PANCREATIC ISLETS

Under the low power objective of the microscope in sections of pancreas stained with hematoxylin and eosin the islets of Langerhans usually stand out as circumscribed, pale, round or irregularly shaped nests varying in size from 25 to 500 microns. Their total number has been variously estimated, 500,000 per pancreas representing a fair average. Their greatest concentration appears to occur in the

tail and body of the pancreas, two locations in which the highest incidence of islet cell tumors is also found. Although the islets of Langerhans are fairly well demarcated from the surrounding acini and ducts, no intervening connective tissue capsule, in the true sense of the word, exists and acini and islet cells appear in close apposition. This fact is not surprising when we consider that the islets are formed from ducts (1) although the process, according to most investigators, is normally prenatal (2).

As seen in hematoxylin and eosin preparations using the high power objective, the islets are composed of small, pale, cuboidal, low columnar or wedge-shaped cells disposed in the form of ribbon like strands, short cords or alveolar groupings, occurring in pure or mixed pattern forms. These cellular aggregations are separated by fine anastomosing capillary blood channels and the vascularity of the islets stands out in striking contrast to the relatively 'bloodless' condition of the surrounding acinar tissue. The blood vessels are accompanied by a certain amount of reticular and fine collagenous connective fibers which impart to the islets large and small degrees of lobulation. The thin basement membranes of adjacent ducts and acini along with the endothelium of small blood vessels and the occasional small connective tissue fibers line the islands peripherally and represent the only suggestion of a capsule as seen in our own and other studies.

Individual islet cells were small and of uniform size each contained a small, round to oval, centrally placed nucleus poor in chromatin and an investing ring of fairly clear cytoplasm. A lack of zymogen granulation and chromidial substance contrasted the pallor of the islet cells with the darker appearance of the surrounding parenchymatous elements. Intimate contact of certain groups of islet cells with sympathetic ganglion cells was observed and Gomori (23) has expressed the belief that these represent special chemoreceptors concerned with the regulation of insulin. As seen in preparations using the Mallory Heidenhain stain the cytoplasm of islet cells was finely granular. In 60 to 80 per cent of the cells the granules were grayish orange. These were the beta cells, the cells concerned, according to

available experimental and pathologic evidence (13) with the metabolism of carbohydrates. In other words these "beta granules" may be the morphologic expression of insulin content. They are insoluble in water but soluble in alcohol, a matter important in selecting a fixative for studies of pancreatic tissue. Twenty to forty per cent of the cells showed the presence of ruby red granulations identifying these cells as the alpha cells of Lane and Bensley. These granules are somewhat soluble in water but they can usually be demonstrated in material fixed in formalin. Remaining cells take a sky blue stain and represent the so called D cells.

In fresh tissue fixed with Bouin's fluid and stained with the Gomori (22) chromium hematoxylin-phloxine stain, beta granules appeared dark blue in sharp contrast to the red color of the alpha cell granulations. D cells could not be differentiated from alpha cells by this method.

Mallory's phosphotungstic acid hematoxylin stain colored alpha granules steel blue but did not bring out the beta granulations. However, inasmuch as it colored the zymogen granules of the pancreatic acini a deep blue-black or purple, it facilitated the distinction between acini and islets. It afforded also a means of studying postnatal acinar origin of pancreatic islets. Our investigation by this method did not show cells containing both zymogenic and specific islet cell granulations. Postnatal formation of islets from pancreatic ducts is conceded by many investigators.

Using these and other methods of differential staining, wide variations were encountered in the numerical proportions of the various cellular types in the islets and the density of the granulations. Even in presumably normal material, margination of granulations and even degranulation were commonly observed. Some of these aberrations represent artefacts based on postmortem autolysis. For the best histologic results, employment of perfectly fresh tissue is essential.

ISLET CELL ADENOMAS WITHOUT KNOWN HYPOGLYCEMIA

In a consecutive series of 10314 necropsies in which the pancreas was made available for

study in 36 cases the presence of one or more clinically silent adenomas of the islets of Langerhans and in 8 cases the presence of 'functioning' adenomas was demonstrated. This incidence of 1 in 234 necropsies represents the 'routine' average and is considerably lower than the figure cited by Pease, whose 500 consecutive cases yielded 8 solitary non-functioning adenomas as a result of a carefully conducted gross and microscopic search for their presence. Twenty-four of the 44 subjects¹ were men and 20 were women. The ages of the patients at the time of death ranged from 27 to 85 years. 91 per cent being more than 50 years of age. Causes of death were varied. Coronary sclerosis and gastrointestinal carcinoma led the list, with no definite clinical or pathologic evidence that hyperinsulinism played even a terminal rôle. Interestingly enough, in 3 of the cases the islet cell tumors developed in spite of the existence of clinical diabetes mellitus.

In these 44 cases there was a total of 52 tumors, 38 being localized in the tail of the pancreas, 3 at the junction of body and tail, 2 in the body proper, and 9 in the head of the gland. In 35 cases the tumors were single, in 8 2 separate adenomas were present, and in 1 the neoplastic process appeared to be truly multicentric—a sort of adenomatosis. In 5 of the 8 cases of 'double tumors' the neoplasms were in close proximity, one to another. In 3 instances the tumors were widely separated.

The diameters of the tumors varied from 1 millimeter to 1.5 centimeters, with an average of 5 millimeters. Only 3 specimens exceeded 1 centimeter in diameter. Grossly the tumors appeared to be encapsulated and sharply demarcated from the surrounding acinar tissue, although separation could rarely be accomplished along a clear plane of cleavage. As compared with the adjacent tissue the color did not contrast so markedly as did the texture of the cut surface, in which the gross lobulation so characteristic of pancreatic parenchyma, was replaced by a smooth homogeneity striking in all islet cell tumors examined in this group.

Histologic features of these 52 adenomas were essentially similar to those detailed for

¹Thirty-six, plus 8 who had nonfunctioning adenomas.

the 'functioning' group of tumors in a subsequent section. Accordingly they will not be described here. Examination of surrounding pancreatic tissue revealed islet cell hyperplasia in 12 instances and proliferation of ducts in 4 cases. Acinar atrophy with fat replacement was noted on 5 occasions and an additional 3 cases showed interstitial fibrosis. In 1 case the phenomenon of squamous cell metaplasia of the pancreatic ducts was demonstrated.

ISLET CELL ADENOMAS WITH HYPERINSULINISM

In 1929 Roscoe Graham achieved the first surgical cure of hyperinsulinism when he successfully removed the causative islet cell adenoma (31). From 1929 to September 1945 we have found in the literature 99 additional and similar examples in which the same result was obtained. Thirty six other and somewhat similar cases are listed under 'personal communication' items and so forth but the data supplied were not sufficient to permit of comparative analysis. A further group of 25 functioning islet cell adenomas has been reported from necropsy studies over the same period.

At the Mayo Clinic from 1927 to September 1945 in 19 cases a diagnosis of clinical hyperinsulinism was based on the presence of benign islet cell tumors which were successfully removed at operation (12 25 36 37 46 55)¹. In 2 additional cases the tumor could not be located at operation and was discovered only after careful search at necropsy. In still another case there existed a condition of diffuse islet cell adenomatosis which was only partially relieved by subtotal pancreatectomy. Thirteen of the patients were female and 9 were male. Their ages ranged from 9½ to 68 years with an average of 41.5 years and with two thirds of the patients listed in the fifth and sixth decades. Symptoms referable to hyperinsulinism had existed for periods varying from 2 months to 18 years. Twelve patients had had trouble for at least 5 years and 5 dated back the onset of their symptoms to periods of more than 10 years. The minimal blood sugar level² was less than 50 milligrams per 100 cubic centimeters in 20 of the 22 cases

and in 16 it was less than 40 milligrams. A minimum of 20 milligrams was recorded in 1 case. The blood sugar level did not reflect any information as to the clinical duration of the trouble.

In 12 of the 22 cases the tumor was more or less easily identified by the surgeon and removed by simple excision. In 3 cases surgical removal of the body and tail of the pancreas was carried out with the hope that the zone of tissue removed included the causative tumor, which were not palpable at operation. In 1 instance this procedure was successful, a small adenoma being found by the surgical pathologist. In the other 2 cases reoperation was necessary the adenoma being found and excised locally in one. In the other case the surgical pathologist made the discovery of a small tumor deeply embedded in a resected portion of the head of the pancreas (Fig 1). In 1 instance total pancreatectomy was resorted to because of undoubted clinical evidence of tumor and the inability of the surgical pathologist to find the adenomas in successively removed portions located deep in the head, close to the duodenum. In 1 of our early cases death of the patient followed an exploratory operation with negative findings. An adenoma involving the head of the pancreas was discovered at necropsy. In another case material from 3 partial resections was devoid of adenomas and the patient continued to suffer from the effects of hyperinsulinism until his death 18 years after the last operation. At necropsy elsewhere an adenoma of accessory islet tissue was found near the duodenum. In 2 cases the surgeon resected suspicious tissue which was reported by the surgical pathologist as being 'negative' for tumor. Relief of symptoms prompted us to review the surgical material carefully. Adenomas measuring 2.5 and 4 millimeters in diameter respectively were found. These represent the smallest hyperfunctioning islet cell adenomas, with surgical cures on record. The twenty-second case was one in which multiple resections have been carried out for adenomatosis of the islets of Langerhans. Inasmuch as this case bears some resemblance to several of an unusual nature recorded in the literature (30, 40) a brief description is appended.

¹Seven of these cases have been reported in the literature by the "W" method.

Fig. Surgical specimen of resected pancreas showing an encapsulated benign islet cell tumor 0.8 centimeter in diameter located in the head. Benign tumors of this type are in general small and in consequence difficult to locate at the time of operation.

A 34 year old white woman had experienced for 11 years transitory episodes of diplopia, faintness, weakness and excessive perspiration. At first infrequent and mild with the progression of time these became frequent and severe. It had been noted that the attacks came on before meals and that they were relieved by the taking of food. Recently the attacks had been complicated by unconsciousness with urinary and fecal incontinence. In several of the attacks there had been convulsive twitchings.

Results of physical examination were essentially negative. Studies on blood sugar during an attack brought on by fasting showed a level of 36 milligrams per 100 cubic centimeters of blood. Determinations of calcium and phosphorus gave values of 13.1 milligrams and 2.0 milligrams per 100 cubic centimeters of serum respectively. In spite of negative roentgenologic evidence it was considered that the patient was suffering from hyperparathyroidism as well as hyperinsulinism. Following operation on September 24, 1943 for removal of a pancreatic adenoma there was transitory hyperglycemia. Soon thereafter the previous symptoms recurred and on April 4, 1944 the entire tail of the pancreas was removed for multiple small adenomas which had not been palpable at the time of the first operation. This second operation cured the hypoglycemic attacks and brought the blood sugar to normal levels as determined repeatedly over a subsequent period of 18 months.

In March 1945 the patient returned for consideration of her parathyroid status. Calcium levels at this time ranged from 12.5 to 13.8 milligrams per 100 cubic centimeters of serum, and phosphorus values varying from 1.9 to 2.5 milligrams per 100 cubic centimeters of serum were obtained. Studies on urinary

excretion of calcium while the intake of calcium was approximately 125 milligrams daily demonstrated a 'negative balance.' There was no evidence of renal calculi or of disease of bone. On March 22, 1945 a typical parathyroid adenoma measuring 2.5 by 1.5 by 0.5 centimeters was found and removed from the anatomic location of the left inferior parathyroid gland. Postoperatively no chemical improvement was noticed in the studies of the blood and at the present time the advisability of surgical exploration of the mediastinum is being considered to climax this most unusual story of probable multiple parathyroid tumors associated with pancreatic insular adenomatosis.

Pathologically the first pancreatic adenoma removed from this patient measured 1.5 centimeters in diameter, was well encapsulated and did not differ materially from others described in this series. Atypical beta like granules were found in abundance. The material from the second operation, on the other hand, showed large zones of pancreatic acinar tissue replaced by a multicentric nodular growth of atypical islet cells. These growths varied in size from microscopic dimensions to nodules 1.5 centimeters in diameter (Fig. 2). At least 8 of the nodules exceeded 1 centimeter in average diameter. Some of the smaller units resembled, microscopically, clusters of giant islets; some of the larger resembled ordinary islet cell adenomas. Everywhere there was evidence of compression atrophy of the surrounding acinar parenchyma. Cellular patterns ranged through all the types to be described in connection with the group of 'functioning' adenomas with no particular cytologic departure. Apparent lack of encapsulation, degrees of local hyperchromatism and the presence of a very occasional mitotic figure were per-

Fig. 2. Benign adenomas of islets of Langerhans with hypernephroma. Two distinct adenomas (one cystic) are shown. In the vicinity are multiple smaller adenomas and several giant islet (hemorrhagic) and eosinophilic islet (X 8).

Fig. 3. The illustration includes the major portion of a functioning adenoma. The capsule is poorly defined. Regions of calcification are apparent (adenoma) in the center (X 9).

haps somewhat unusual features but the condition was adjudged to be benign.

To our knowledge this represents the third case of hyperfunctioning pancreatic insular adenomatosis and the first with associated parathyroid adenoma (probably multiple). The pathologic findings in our case suggest the multicentric origin of certain of these tumors and accordingly the possibility of neoplasia in that portion of the pancreas not removed at operation. Only long follow up studies on these cases will establish the basis for ultimate prognosis.

Tumors encountered in this group were single in 22 cases and in 1 case multiple—detailed in foregoing paragraphs. Six of the single tumors were definitely located in the tail of the pancreas and an additional 5 were found at the junction of the body and tail of the gland. Nine of the tumors were found embedded deep in the head of the pancreas. An ectopic site was established in 1 case in which repeated resections had failed to reveal the presence of the adenoma and in the remaining case multiple tumors were present in the tail of the gland. Correlating the location of the adenomas with the nature of the operative procedures effecting their removal it was found that a location other than in the body or tail of the pancreas usually necessitated subtotal or total pancreatectomy in one or more stages. The diameters of the tumors varied from 2.5 millimeters to 6 centimeters (Fig. 3).

16 of the 22 adenomas lying between the limits of 1 and 2 centimeters. The 2 largest measured 3 and 6 centimeters in diameter respectively and 4 of the adenomas measured less than 1 centimeter of average thickness. It is most unusual for an adenoma of a size smaller than 5 millimeters to be productive of clinical hypernephrosis. Two of our tumors were unique in this regard as pointed out previously. A more or less complete fibrous or fibroelastic tissue capsule delimited 13 of the adenomas from the surrounding pancreatic tissue. In 7 instances the capsule was poorly defined, very thin or present over only a portion of the tumor. In 2 no capsule whatsoever could be demonstrated. It was accordingly felt that the absence of an investing capsule should not negate the diagnosis of an otherwise bona fide example of islet cell adenoma.

On cut surface the tumors had a pinkish or grayish color and more or less homogeneous smooth texture unlike the lobulated appearance of the surrounding gland. The consistency was somewhat firmer than that of the normal pancreas but the difference was not such as to be practically helpful in locating small and deeply lying tumors of this type. It is not surprising that a fair proportion of islet cell adenomas are found only after careful examination in the pathologic laboratory of large segments of resected pancreas. Hyaline degeneration and fibrosis were grossly apparent as degenerative changes in 5 of the tumors in this

Fig 4 Histologic details of an adenoma which demonstrated a predominance of the so-called ribbon type of architecture. Note anastomosing bands of large columnar cells which here and there seem to line the thin walled and richly provided vascular channels (hematoxylin and eosin $\times 100$)

Fig 5 This adenoma is again poorly encapsulated. Its cells are disposed in tubular and alveolar fashion. The marginal transition between the ducts, the acini, and the tumor cells is more apparent than real (hematoxylin and eosin $\times 100$)

group. An associated capsular thickening was evident. Extensive hyaline changes appeared to be fairly well correlated with a long preoperative duration of choled symptoms. In 2 of these hyalinized adenomas calcification was additionally present (Fig 3) the tumors being definitely gritty. Calcification without gross hyaline change was noted in 3 other instances.

Histologic and cytologic observations. Except possibly in the matter of specific granulation the microscopic observations herein made apply equally to the functioning and the non-functioning adenomas. The following notations however except when otherwise stated refer to the secretory group described in this study.

In general the tumors can be considered structurally in the light of gigantic islets faithfully reproducing on a large scale the normal aspects and structural relations of the islets of Langerhans. In most instances some normal features are exaggerated and repeated over and over giving the tumor a definite overall histologic appearance. As stained by the ordinary hematoxylin and eosin method and viewed under moderately low magnifications the appearance in all of the tumors was that of typical or atypical islet cells disposed in long or short anastomosing cords, ribbons or strands one to four cells thick. In the majority of the tumors the so called ribbon (trabecular) pattern predominated (Fig 4) in

others an alveolar (Fig 5) tubular or rosette arrangement was the rule and in still others the appearance of short stubby cell cords imitated the picture of the simple solid type of architecture described by Isaaji. However so frequently did the different patterns occur side by side that it was felt that no useful purpose was to be served by classifying them as separate entities. Arrangement of cells was orderly and difference of cell size not appreciable in any given adenoma.

Coursing everywhere among these anastomosing bands of tumor cells were small thin walled capillary blood vessels. Except in those instances in which fibrous or hyaline material formed a large bulk of the tumor tissue the adenomas were richly vascular. A delicate fibrous connective tissue framework accompanied the blood vessels and appeared condensed in the form of a thin or thick capsule about the periphery of the tumor where the surrounding pancreatic acinar and duct tissue was frequently compressed. In some tumors this capsule was incomplete or absent. Focally or diffusely in fifteen tumors the collagenous framework was coarse and heavy with compression of capillaries and cords of tumor cells alike. Regions of hyalinization were always present in these fibrous examples and in 5 instances calcification was found in scattered regions. Hyalinization and calcification in general tended to represent degenerative changes

TABLE I.—HYPOGLYCEMIA ISLET CELL CARCINOMA WITH METASTASIS
COLLECTED CASES FROM THE LITERATURE

Case	Author and year	Age years, and sex	Minimal sugar mg per 100 c. of blood	Survival after onset of symptoms and post-operatively	Pathologic data				
					Site number and size cm.	Atypia and mitoses	Location of vessels	Metastasis	
								Liver	Other sites

*Reported also by Brennand, Gomori and Cusum (quoted by Gray 36).

†Reported also by Joslin.

Note: In addition to those and Banks (48) he collected seven cases for the literature in which there are no chemical data to establish the diagnosis of hypercholesterolemia. These are: Fabozzi (30) four cases, Zisette (37) one case, Haman (42) one case, Kowaguchi (1935) one case. It also were Duff and Murray's three cases in which hypoglycemia was known to be absent. Frank (36) reported two cases of carcinoma of the pancreas without hypoglycemia, one of them with metastasis. In the other case the patient, apparently free of spread at time of operation, underwent resection of body and head of the pancreas together with pylorus and duodenum. She is reported not to show evidence of recurrence two years after operation.

affecting tumors of long standing as judged by the clinical history. Guttulate deposits of calcium were occasionally noted.

Under higher magnification the individual cells in these adenomas were also strikingly similar to those of normal islets. They were small and varied in appearance from polyhedral through cuboidal prismatic and columnar shapes, depending on their position in the cords and lobules. In adenomas with the ribbon type of architecture the cells tended to be predominantly columnar and to lie in a direction transverse to the long axis of the ribbon. In those tumors in which alveolar clusters and pseudorosettes were prominent centrally located elements were mostly rounded and polyhedral while peripherally lying cells assumed a columnar appearance. An intimate contact with the vascular capillary network was noteworthy but invasion by tumor of vascular channels was not observed in this group (Fig 6). The cytoplasm of the islet cells was small in amount eosinophilic and nongranular in ordinary hematoxylin and eosin preparations. In degenerated regions it was sometimes voluminous vacuolated and hydropic.

The nuclei were in general indistinguishable from those of normal insular cells being small spherical or ovoid and poor in chromatin. Occasional giant forms were observed. True mitotic figures were very infrequently found but many doubtful examples were seen representing pyknotic chromatin particles associated with degenerative changes in the tumors. Nucleoli were small when observed.

Specific granulations Using the three special stains mentioned in a foregoing paragraph it was found that in two of the tumors typical beta granulations were seen in the cytoplasm of the majority of cells. In 18 tumors at least a few of the cells contained fine granular material which we considered as atypical beta granulations. In some it was dustlike in some fragmented and dispersed and in others condensed and margined as though the cells were undergoing a process of degranulation (Gomori 22). In fresh material fixed in Bouin's fluid the granulation always appeared more typical than in the older formalin fixed specimens which furnished us with the

Fig 6. Projection of tumor tissue into the surrounding pancreatic parenchyma. The cells are somewhat more anaplastic than those depicted in Figures 4 and 5 and there are occasional mitoses. Although there is an entire lack of encapsulation the absence of blood vascular invasion indicates that metastasis is unlikely. The tumor illustrates the salient features of our grade 1 carcinomatous group (hematoxylin and eosin $\times 75$).

bulk of our tumors. In fact the cells in these older tumors often failed to show more than a minimum of granulation. Well stained alpha cells were seen in but 2 of the specimens where they constituted about 2 per cent by actual count. (In the necropsy series they were found more frequently.)

METASTASIZING ISLET CELL CARCINOMA WITH HYPERINSULINISM

When one considers the cellular dedifferentiation which is manifest in the growth of a metastasizing carcinoma it is surprising to note that the anaplastic cells of islet cell carcinomas can produce insulin and clinical hypoglycemia. Yet according to Hanno and Banks such a clinical effect had been observed in about half of the cases recorded up to 1943. We have abstracted from the literature (Table I) 16 cases of metastasizing and 'hyperfunctioning' islet cell carcinomas of which 4 (10 15 35 56) have been seen at the clinic. Details of a fifth case (Case 17 of Table I) probably falling into this group are presented chiefly because of the highly malignant character of the growth a feature but rarely encountered in reported cases.

A 42 year old man (Case 17 of Table I) was admitted to the hospital in stupor which rapidly progressed into coma with high fever death ensuing

Fig 7 Metastasizing adenocarcinoma, grade 2, of the islets of Langerhans. Apparent features are the large size and the diffuse infiltration of the tail of the pancreas (hematoxylin and eosin, $\times 4$)

within a matter of 48 hours. The history of his trouble had dated back 2 months to an onset with intractable abdominal pain which extended to the lumbar portion of the spinal column and down into the testicles. Morphine was given with only intermittent relief. One month after the onset of the pain additional symptoms in the form of intermittent contractions of different groups of voluntary muscles became manifest. Episodes of rigidity leading to opisthotonos occurred and these were sometimes relieved by the taking of whisky. Three weeks before admission there developed paralysis of the right facial muscles and weakness of the right arm. Deterioration of the patient's mental status with confusion and delirium were terminal complications.

The picture on examination was that of an unconscious, very restless patient with marked nuchal rigidity and right hemiparesis. The clinical impression was that of meningitis of undetermined origin. Studies of cerebrospinal fluid showed a sugar content of less than 20 milligrams per 100 cubic centimeters. The concentration of sugar taken on admission (non fasting) was 60 milligrams per 100 cubic centimeters of blood. With a temperature that rapidly rose to 107 degrees F the patient lapsed into coma and died.

The findings at necropsy performed 3 hours after death were remarkable and included carcinoma of the tail of the pancreas (Fig 7) with involvement of peripancreatic nodes, celiac nodes, liver, left kidney, cauda equina and lumbar portion of the spinal cord. The remainder of the spinal cord and the brain failed to show metastasis.

Macroscopically the tail of the pancreas was diffusely involved by a neoplastic process which was infiltrative and in no part delineated by a capsule. The cellular clarity in form and architecture was lost. The cells of normal islets were present in small numbers and hyperchromaticism of many

Blood capillaries were numerous and thin, lying in close proximity to irregular bands of tumor cells which here and there showed actual intravascular invasion. Some large veins likewise demonstrated invasion by groups of neoplastic cells. Special stains employed to substantiate our diagnosis of islet cell carcinoma brought out the presence of fairly typical beta granulations in some of the more differentiated tumor cells. These granules were also demonstrated in the metastatic deposits.

Analysis of all 17 cases of metastasizing and hyperfunctioning islet cell carcinomas brings out the following pertinent data. The age of the youngest patient was 18 and of the oldest 73 years with an average of 47.8 years.¹

Ten patients were in the 40 to 60 year age bracket. There were 12 men and 5 women. In all of 15 cases wherein adequate clinical information was available, spontaneous hypoglycemia was present, usually in severe degree. In 2 cases there was a history of diabetes mellitus preceding the onset of the symptoms of hyperinsulinism.

One symptom in all cases was a unique and characteristic. In 9 of 10 cases there were tabular pounds (73 to 150) and usual symptoms of hypercaloric intake, hypoglycemia, and a majority of the patients had the underlying ab-

normal weight, as in the case of carcinoma, characteristic disorders wherein ranging from were noted, evidence of the failure to prevent the result was masked. J. J.

Fig. 8. Same case as in Figure 7 showing invasion of a periaortic lymph node. There is a certain resemblance to normal islet architecture but the cells are hyperchromatic and otherwise anaplastic (hematoxylin and eosin $\times 100$).

Fig. 9. Same case as in Figure 7. Hepatic metastasis from adenocarcinoma, grade 2, of the islets of Langerhans. Cellular anaplasia and mitoses are apparent features (hematoxylin and eosin $\times 210$).

that 5 of the tumors occurred in situations near enough to the common bile duct to effect obstruction to the outflow of bile. This is in contrast to the situation existing in cases of ordinary pancreatic carcinoma in which as a result of perineural invasion by malignant cells a physiologic blocking of the common bile duct results.

Average survival after development of these symptoms was about 1 year with 4 weeks and $4\frac{1}{2}$ years representing the extremes. Surgical procedures employed in these cases consisted of exploration only in 2, exploration plus biopsy in 9 and partial pancreatectomy in single or multiple stages in 2. In 4 cases the condition was discovered at necropsy.

Pathologically in 2 of the cases observed at the clinic the growth was diffuse involving the entire pancreas; in 1 the head of the pancreas was spared by a growth which extensively involved the remainder of the gland. In one there was diffuse infiltration of the tail only and in the remaining instance the process took the form of two poorly circumscribed nodules 6 centimeters and 2 centimeters in diameter located at the junction of the body with the tail of the gland. The tumors were all very large compared with their benign counterparts and they lacked any semblance of encapsulation. Involved segments of pancreas were grossly thickened, firm, nodular and often fixed by infiltration of surrounding tissues. Surfaces made by cutting revealed a

grayish or grayish pink firm tissue lacking the lobulated appearance of the normal pancreas. Red regions of necrosis and hemorrhage were seen in 3 of the tumors. Metastatic deposits in lymph nodes and liver often showed more extensive necrosis than the primary lesion. The presence of hepatic metastasis was demonstrated in all 5 cases; peripancreatic lymph nodes and omentum were additionally invaded in 3 and in 1 case metastasis was generalized.

Microscopically in the 5 tumors we were privileged to study the essential composition was that of islet like cells disposed more or less in the manner described for benign adenomas but with marked irregularity of size, shape and staining properties. Outstanding points of difference were (1) the occurrence in all the tumors of mitoses in numbers up to 5 per high power field; (2) the presence of atypical mitoses, some of giant or otherwise bizarre configuration; (3) the presence of large nucleoli in almost all of the tumor cells; (4) invasion of large or small vascular and lymphatic channels observed in every instance (Fig. 10) and (5) the occurrence of necrosis and hemorrhage.

Using Broders' method of grading malignancy it was found that 3 of the tumors were of grade 2 and 2 of grade 3. The microscopic picture in the metastatic deposits resembled that of the primary lesion. Some of the pulmonary and hepatic secondaries were extremely vascular with numerous tumor thrombi in venous blood channels. Results of

Fig. 6. Metastasizing adenocarcinoma, grade 3, of the islets of Langerhans. The outstanding feature here is the invasion of large vascular sinus by manifestly malignant cells. This phenomenon of vascular invasion seems in general to be limited to those lesions exhibiting a grade (Broders) of malignancy higher than 1. It may be very important criterion of metastasizing propensities in islet cell neoplasms (hematoxylin and eosin $\times 386$).

special stains designed to bring out beta and other granulations were indecisive except in the single case previously mentioned. In several of the other tumors atypical dustlike particles were seen in certain of the cells.

Metastasizing islet cell carcinoma¹ is a fatal disease with no patient in the literature surviving for more than 5 years after onset of symptoms. The average life expectancy from available data is 11.9 months. It is accordingly interesting that the case with the longest survival was one of two in which surgical attempts were made to remove the tumor.

Surgical exploration was performed at the clinic in 1939 and a diagnosis of adenocarcinoma, grade 3 was made on some tissue removed from a large nodule

Hanno, Frantz, and Duff and their co-authors have reviewed the literature on a few cases in which undoubted islet cell carcinomas were not associated with clinical evidence of hyperinsulinism. Discussed also in these reports are several cases in which the evidence for hyperfunction of the tumor was debatable. In our series we have not seen an example of this rare type of tumor.

lar pancreatic tumor. With this fresh tissue report the surgeon decided against an attempt at removal. Three months later at another clinic the tumor, still without visible metastasis, was removed and reported as being an islet cell tumor of questionable malignancy. Temporary clinical improvement followed. However 1 year later at a third operation the original pathologic opinion was confirmed with the demonstration of hepatic metastasis (12). The patient died in December 1943 following total pancreatectomy with excision of a metastatic hepatic nodule of tumor tissue.

The early history in this case emphasizes the fact that the presence of hepatic metastasis does not always constitute the *smoking gun* of malignancy in certain islet cell tumors, as had been previously supposed. It further emphasizes the possibility of temporarily ameliorating by surgical means the symptoms of hyperinsulinism (25) in patients suffering from the effects of carcinoma of the islets of Langerhans.

HISTOLOGICALLY BORDERLINE CARCINOMA OF THE ISLETS OF LANGERHANS WITH HYPERINSULINISM

We now consider separately a group of functioning islet cell tumors the characteristics of which were such as to place them in the twilight zone between the simple adenomas and the frank metastasizing islet cell carcinomas discussed in a foregoing section. Frantz has reviewed 26 such cases from the literature and has expressed doubt whether some of them constituted truly malignant neoplasms. In general the tumors have shared certain features of frank carcinomas, such as large size, lack of encapsulation and invasion of surrounding pancreas and of small blood vessels. Cellular anaplasia and the presence of mitotic figures were further features removing the tumors from the "garden variety of simple islet cell adenomas." Yet although recurrences have been reported following operation for removal of tumors of this type, metastasis has been lacking. Accordingly it is without surprise that we find them variously designated as adenocarcinoma, grade 1, questionably malignant adenomas, low-grade malignant adenomas and so forth. To the 26 examples cited by Frantz we wish to add pertinent clinical and pathologic data concerning 11

studied from the material seen at the Mayo Clinic. Six of the 11 patients were men and 5 were women. The average age at the time of examination was 37.6 years, the youngest patient being 21 and the oldest 61 years of age. Six were in the fourth decade of life. Symptoms similar to those noted for the benign functioning group had been present for periods varying from 1 to 8 years with an average of 3.5 years. Thus as compared with our benign "functioning" tumors the borderline neoplasms occurred in patients who were 3.9 years younger on an average. Moreover, by the same comparison the symptoms were so serious and progressive that they brought the patient to seek medical treatment in half the time period established for the benign group. These findings are in accord with similar data supplied by Frantz. Minimal blood sugar levels were somewhat higher than those found in the frankly malignant and somewhat lower than those reported in the cases with simple functioning adenomas.

In 10 of the 11 cases operation was performed, the tumors being found with fair ease and excised widely in all instances. In 1 case recurrence of symptoms necessitated a second operation which failed to reveal residual tumor. *The patient continues to have trouble.* A second patient suffered from recurrence of symptoms 8 years after removal of his tumor and died shortly thereafter. No necropsy was performed to rule out the possibility of metastasis. Two of the 10 patients died from postoperative complications. The remaining patients have been followed through symptom-free intervals varying from 4 months to 5 years but this group is too small and the periods of postoperative observation are too short for far reaching conclusions to be drawn as to clinical benignity or malignancy.

One tumor was found at necropsy. Compared with those of the benign series the tumors were large, with fissions in 6 cases attaining diameters of 2 centimeters or more. Single tumors were encountered in 10 instances and in 1 patient the process was multicentric. The body of the pancreas was given as the location for 6, the junction of the body and tail for 4, and the tail for the remaining 2 tumors.

Grossly apart from their larger size, the tumors did not differ markedly from their "simple" counterparts except in the matter of encapsulation which was completely lacking in one and partially lacking in the remainder, 10 of the tumors demonstrating gross invasion of the surrounding pancreatic tissue.

Microscopically all of the tumors showed cellular atypia with a tendency toward large cells. Hyperchromatism of nuclear elements was also universally noted focally or diffusely with some of the nuclei assuming giant unilobulated and multinucleated forms. In one neoplasm mitotic figures were very few, in the remainder they were found with moderate ease, averaging perhaps 1 in every 5 "high dry" fields examined. None was atypical or "pathologic" (so-called x and y forms). Nucleoli were in general prominent but the "bird eye" variety so commonly seen in the metastasizing group was rarely observed here. Invasion by tumor tissue of small venous channels was definitely observed in 3 instances. In 1 of these cases in which there was recurrence of symptoms in 8 years followed by death metastasis may have occurred eventually. In the second and third instances sufficient time has not yet elapsed to permit of final judgment. Some degree of hyalinization was present in all the tumors in this group and as with calcification—a change noted in 6 of the 12 neoplasms—it tended to increase with the age of the tumor as judged by the "functioning" span of its clinical life history.

Examination of 12 tumors using special staining techniques revealed cytoplasmic granularity in 8, in 3 of which the granules identified could be considered as being atypical beta. In 1 case a few alpha granules were seen. The remainder were either agranular or contained a few basophilic fragments of uncertain status.

From a purely cytologic analysis it would appear that these lesions were of grade 1 (Broders) malignancy (Fig. 6). Unfortunately in support we cannot offer undoubted clinical or pathologic evidence of metastasis. In our metastasizing islet cell carcinomas the grade of the lesion was always 2 or higher and in 1 of these cases metastasis was not present at the time of the first operation. In the borderline series the grade never exceeded 1 and in

TABLE II.—LOCATION OF TUMORS

	Cases	Tumors	Tail	Islet body and tail	Body	Head	Ectopic
Nonfunctioning group	44	5	23	3		9	
Clinically functioning adenomas	22	24*	7+*	5		0

Functioning but nonmetastasizing carcinomas	11			4	6		
Total	82	34	33	12	6	9	

*As one case multiple tumors, which could not be counted, were present.

†The two diffuse tumors involved the entire pancreas.

only 3 was there evidence of invasion of veins. We feel consequently that venous invasion in any islet cell tumor and cytologic evidence of a grade of malignancy higher than 1 (Broders) are at present the most important microscopic indexes we have by way of correlating the histologic appearance of the tumor with its metastasizing capabilities.

COMMENT

Incidence. Tumors of the islets of Langerhans are rare but the recorded incidence of their occurrence varies considerably depending on the diligence of the search for their presence. Their frequency has been estimated to be from 1 in 800 to 1 in 1,000 considering necropsy material. Pappenheimer found 5 islet cell adenomas in 4,000 pancreases studied routinely at necropsy. Winters, Gottardo and McNealy at the Cook County Hospital studied material from 13,000 consecutive necropsies and failed to find a single tumor of this type. The incidence in 10,314 necropsies performed at the Mayo Clinic was 1 in 234 cases, and we have previously mentioned Dr Pease's experience with a group of 500 glands in which meticulous search yielded 8 islet cell adenomas. Six of these were of such a small size as to be easily missed on routine gross examination of the pancreas. None of Dr Pease's tumors was clinically active.

The great majority of functioning islet cell tumors furnish material for the surgical rather than the necropsy pathologist. In this functioning group it is very difficult to arrive at

any definite figures of incidence. Including our own series we have accepted the following as representing the total reported in the period from 1927 to 1945: (1) hyperfunctioning adenomas¹ removed at operation 113 cases (36 additional with insufficient data); (2) hyperfunctioning adenomas found first at necropsy 36 cases;² (3) nonmetastasizing but cytologically malignant islet cell tumors (combined surgical and necropsy statistics), 37 cases; (4) metastasizing islet cell carcinomas with clinical evidence of hyperfunction, 17 cases; (5) nonfunctioning islet cell carcinomas with metastasis 6 (?) cases.

In comparing the different groups the average ages of patients in our series show significant differences, namely (1) nonfunctioning adenomas 55+ years, (2) functioning adenomas 41.5 years, (3) functioning, cytologically malignant but nonmetastasizing group 37.6 years, (4) metastasizing islet cell carcinoma group 34.6 years.³ It thus appears that the more active the tumors cytologically and physiologically the earlier they become manifest.

Men and women were equally affected (41 men and 41 women in the entire series studied.)

Clinical symptoms. These are well known and have not been emphasized in the present analysis. It should be mentioned, however, that, paradoxically enough, the more cytologically dedifferentiated the tumor the more severe the symptoms and the shorter their duration. The paradox of marked gain of weight has particularly been stressed as a symptom in the frank carcinoma group. As previously noted, this symptom has frequently masked the seriousness of the underlying condition.

Location of tumors and incidence of multiple tumors can be seen in Table II.

The high relative incidence of nonfunctioning islet cell adenomas in the tail of the pancreas is paralleled only in a general way when we consider the functioning examples. In the literature 30 of a group of 86 functioning adenomas were listed as occurring in the

In 5 cases hyperfunctioning adenomas or carcinomas have been found in extrapancreatic (aberrant) locations.

*The clinical course and symptoms in these cases were identical with those of the previously presented surgical group.

†Average 47.8 years for all seven cases in the literature.

tail of the pancreas. In the same series the body and the junction of the body and tail were the sites of seventeen and thirteen tumors respectively. The statistical chances therefore of a functioning adenoma arising in a portion of the gland which is not too difficult to resect are about 70 per cent!—a practical observation of use to the surgeon who faced with the undoubted clinical evidence of hyperinsulinism in his patient is unable to palpate the causative tumor at surgical exploration.

In the matter of multiple tumors the functioning adenoma group may again be considered as being representative. Our incidence of approximately 5 per cent stands against 10 per cent observed in the literature (based on 100 consecutive case reports). Both figures are somewhat lower than the incidence of multiple tumors observed in the nonneuretic group found routinely at necropsy. Although multiple tumors are usually found in the same general region of the gland they may sometimes be widely separated. The surgeon who finds and removes a functioning adenoma has still an important duty to perform in carefully palpating the remaining portions of the pancreas in search for additional tumors.

Even in the matter of locating solitary functioning adenomas of the islets of Langerhans success does not by any means always reward the primary search. As indicated in our paper in only 12 of our 19 surgical cases wherein an adenoma was proved to exist, was cure accomplished by the first operation. If we add to the remaining 7 a group in which exploration gave negative results and in which the patients did not return for further surgical operation it appears that perhaps only half of our patients were cured by the first surgical attempt to locate and remove their tumors. Accordingly the present-day surgical tendency is to accept good clinical evidence as being indicative of the existence of a pancreatic islet cell tumor and failing in a search for its presence, to resect the more easily accessible portions of the pancreas known frequently to contain the tumors. This procedure has

proved valuable in our series. Removal of remaining portions of the pancreas can be accomplished later for recurrence of symptoms. Occasionally as indicated the causative tumor will involve heterotopic pancreatic tissue.

Individual islet cell tumors were with few exceptions small a matter which makes for difficulty in their identification at the time of surgical exploration of the pancreas. A diameter of 5 millimeters can generally be taken as the minimum necessary for the production of clinical hypoglycemia. Only 2 of our 'functioning' tumors failed to exceed this average size. Rarely do the functioning adenomas attain large size and when they do the bulk of the tissue is made up of fibrous and hyaline elements. The frankly metastasizing carcinomas, as a group are much larger than the benign 'functioning' tumors, the cytologically active but nonmetastasizing group providing tumors of intermediate dimensions. The nonfunctioning group range in size from 1 millimeter providing the smallest tumors in the series.

Texture color encapsulation and so forth. Trends rather than actual measurable gross differences spanned the variations noted in the different groups listed in the foregoing. Frankly malignant islet cell tumors were soft brown or brownish red hemorrhagic, and non encapsulated with gross evidence of centrifugal spread into the surrounding normal pancreatic parenchyma. Nonfunctioning tumors and benign functioning adenomas were in general grayish and firm with fairly clear delineation if not actual encapsulation. Adenomas which proved to be cytologically active or 'borderline' tended to be poorly encapsulated but in general could not be grossly separated as a group.

Microscopically whether the tumor was benign or malignant a certain resemblance of the cells and their arrangement patterns to that of normal islet cells made identification of the tumor simple. An intimate relation of tumor cells to a rich network of capillary blood vessels was noteworthy even in tumors which had undergone hyaline and calcareous change. An arrangement of tumor cells in the form of islands, acini cords, strands, or ribbons was frequently noted with all pictures

However the "statistical" evidence has been based on tumors found at operation and the proportion of operations in which the tumor has been found has been about 50 per cent. It is probable that the actual incidence of functioning tumors involving the head of the pancreas is considerably higher than the figure given.

represented in certain tumors. Although the ribbon type of architecture predominated, we saw no useful purpose in subdividing the tumors into different types based on these minor differences of cellular architecture. Development of fibroblastic stroma and the formation of an investing capsule varied greatly. Whereas in general the more cytologically active tumors were most poorly demarcated many benign tumors seemed also to invade the surrounding pancreas. In attempting to determine microscopic criteria of malignancy our efforts were only partially successful as witnessed by our segregation of a group of 'borderline' tumors. It appeared however that the metastasizing group possessed the following characteristics (1) malignancy of a grade higher than 1 as determined by the method of Broders, with cellular atypia, hyperchromatism, loss of 'polarity' and the presence of normal and atypical mitosis (2) invasion of venous channels. The "borderline" group showed cellular activity with mitosis atypical cell forms and hyperchromatism of a degree commensurate with the diagnosis of carcinoma, grade 1 by the aforementioned method. Invasion of veins occasionally seen in this group may place the tumor in question in the category of a possible metastasizing neoplasm. The frankly benign examples showed neither mitotic activity nor venous invasion. From this tentative classification it will be seen that invasion of veins by tumor cells is the all important criterion which should be sought for as the determining factor in the possibility of extrapancreatic spread of islet cell tumors.

In the matter of using special cytologic stains as a means of differentiating functioning from nonfunctioning adenomas and both of these groups from malignant islet cell tumors, our efforts proved somewhat disappointing. Even dealing with fresh material which yields the best results we were unable to substantiate the claims of others in this regard. In other words, we found beta granulations in non-functioning adenomas and failed to detect their presence in tumors producing marked clinical evidence of hyperinsulinism. The granulations found were as indicated often atypical.

SUMMARY

Asymptomatic islet cell adenomas are more frequent than hitherto believed. Routine examination of 10,314 pancreases revealed 41 such tumors and a carefully conducted study of 500 pancreases disclosed 8 tumors (1.6 per cent).

Clinical hypoglycemia originating in neoplastic proliferation of islet cells is a rare disease. Such proliferation can be manifested 4 ways pathologically (1) benign adenomas, 70 per cent (2) islet cell adenomatosis, 2 per cent (3) histologically malignant but non-metastasizing islet cell tumors, 20 per cent, (4) metastasizing islet cell carcinomas, 8 per cent.

Generally productive of a clinical history measured in half decades, the adenomas are small, fairly well encapsulated nodules with high degrees of cellular differentiation and no mitosis. The histologically malignant or "border line" tumors are on an average twice the size of the adenomas and are more vascular and more invasive. The presence of cellular atypia, hyperchromatism and mitosis is that of a grade 1 (Broders) order of malignancy and is paralleled in a general way with a relatively short clinical history. The possibility of metastasis should be considered in members of this group in which vascular invasion is present. Measured in clinical terms of months rather than years and sometimes of production of a paradoxical gain in weight, metastasizing islet cell carcinomas demonstrate a large size, gross invasive tendencies and metastasis with microscopic evidence of manifestly malignant cells and vascular invasion. In all of the groups positive results using special staining methods will be obtained in some but not all of the tumors. The results do not justify the conclusion that functioning pancreatic islet tumors are beta cell neoplasms.

Statistically speaking the surgeon can expect to find a tumor in from 50 to 60 per cent of the cases on the first exploration. The presence of multiple tumors (10 to 15 per cent in the benign group including adenomatosis and from 15 to 20 per cent in the borderline and the metastasizing malignant groups) will sometimes decide the necessity of repeated operations in search for the causative tumor (per

sistence of hypoglycemia after partial pancreatectomy for hyperfunctioning tumor)

Blind resection of the tail of the pancreas will remove 50 per cent of the tumors resection of the body as well as the tail will account for about 20 per cent more. Total pancreatectomy will occasionally be necessary for some of the small buried tumors located in the head of the gland which is the site of about 20 to 30 per cent of the neoplasms. Very rarely (1 to 2 per cent) the tumor will have an extra pancreatic location

The surgeon performing an operation for the relief of hypoglycemia must be prepared to carry out procedures ranging all the way from simple excision of an easily identified and readily shelled out tumor to total pancreatectomy. These procedures are justified by the complete failure of medical treatment of organic hypoglycemia.

APPENDICITIS COMPLICATING PREGNANCY LABOR AND THE PUERPERIUM

RICHARD L. MEILING M.D., Columbus, Ohio

ACUTE appendicitis is a most serious abdominal disease complicating of pregnancy endangering the lives of both mother and child. Crossen and other authorities have stated that 80 per cent of all cases of acute appendicitis complicating pregnancy occur during the first 6 months of gestation. The rarity with which term labor or the puerperium are complicated by acute appendicitis is most striking. Norton and Connell reported but 1 case of term labor complicated by acute appendicitis in 20,000 deliveries at the Margaret Hague Hospital. These same authors collected from the literature and their own hospital records 110 cases of appendicitis complicating pregnancy and from this series they reported only 9 cases as a complicating problem of labor or the puerperium. Thus, it is readily seen that it is highly problematical that any one observer will personally see or attend very many of these cases, nor will he have any large or extensive experience in the treatment of this surgical and obstetrical problem. The recent advancements in surgical procedures, gastrointestinal decompression, intravenous nutrition and the chemotherapy and antibiotic therapy in the treatment of appendicitis, appendiceal peritonitis, and puerperal sepsis warrant continued review of the approach to this serious obstetrical and surgical problem if the optimum in both surgical and obstetrical treatment is to be achieved.

Historically we are familiar with the young French surgeon M^{lle}ier's attempt in 1827 to guide the surgical approach to the treatment of inflammation of the vermiform process, and only to have the great Dupuytren thwart and crush his efforts. The American pathologist

Reginald Fitz, is credited with solving the riddle of appendicitis in the year 1886. To another American P. F. Mundé, the famed New York obstetrician and gynecologist, we are indebted for the first report in 1894 of acute appendicitis complicating pregnancy.

During the succeeding 52 years, a considerable volume of medical literature has been presented concerning this surgical and obstetrical problem. Several American and European authors have collected rather extensive series of cases, most notable in this group are the articles by Hilton, Schmid, Jerlov, Heinicke, Garcia, D'Ermeo, Macs, and Norton and Connell.

The reported incidence of pregnancy complicated by appendicitis varies slightly with the various authors. Mussey and Crane, at Mayo Clinic, reported a high of 2 per cent. Schmid found the incidence in his series collected from the German literature to be 1 per cent. Cosgrove in 1937 reported an incidence rate of but one case in each 1,380 deliveries at the Margaret Hague Hospital. Johnson, in reviewing the problem in Australia, came to the conclusion that the incidence of acute appendicitis in women in the childbearing age is the same rate irrespective of whether the patient is pregnant or not. Findley found that 70 per cent of all women who have appendicitis without operation will suffer from this disease during subsequent pregnancies. Tashiro and Zinninger at Cincinnati General Hospital have verified recently the preponderance of acute appendicitis occurring in the male. They found 66.1 per cent of their series were male patients and 33.9 per cent female.

The accepted clinical signs and symptoms, as well as the established laboratory findings used in making the diagnosis of acute appendicitis, are considerably altered or masked in the presence of pregnancy. As early as 1903, Fueth called attention to the anatomical displacement of the cecum and the appendix

From the Department of Obstetrics and Gynecology, Western
Hospitals of Cleveland, Western Reserve University School
of Medicine.

Presented before the Obstetrical and Gynecological Section of
the Cleveland Academy of Medicine, February 9, 1947, Cleve-
land, Ohio.

during pregnancy. The roentgenological studies of Baer Reis, and Arens of this country and Guthman and Staehler of Germany have confirmed this displacement. Usually, lateral and cephalic displacement begins at the end of the third month of gestation and by the end of the sixth month the appendix and cecum are no longer pelvic organs, but rather abdominal organs. Their return to the normal anatomical position in the pelvis occurs between the tenth and twelfth postpartum days. This displacement results in the masking of the signs of muscle rigidity, rebound tenderness, psoas spasm, maximum tenderness over the McBurney point, and acute tenderness in the iliac fossa elicited on rectal examination.

Urinalysis during the early stages of the acute phase of cystitis or pyelitis often reveals little or nothing of a pathological character. Hence, the predilection to right-sided pyelitis and hydronephrosis complicating pregnancy assumes added significance in the differential diagnosis with acute appendicitis, particularly after the sixth month of gestation.

Nausea and vomiting of pregnancy are difficult to distinguish from that caused by peritoneal irritation associated with an acutely inflamed appendix. Tashiro and Zinninger found 41.9 per cent of the patients with acute appendicitis presented histories of nausea and 67.1 per cent histories of emesis. Constipation and the resultant use of laxatives during pregnancy makes the evaluation of the gastrointestinal tract activity even more confusing.

Homans states that a leucocytosis of between 10,000 and 20,000 is usually associated with acute appendicitis. Tashiro and Zinninger found in their series that the leucocyte count with acute appendicitis averaged 15,800 and with perforation 15,100 to 17,400. Virchow's "physiological leucocytosis of pregnancy" has been reported by Carey and Litzenberg to be between 8,700 and 10,000 rarely exceeding 12,500. Baer on the other hand has found the leucocytosis during labor will average 18,000 but may reach the high of 32,000. Vogt reported a progressive increase in the blood sedimentation rate during pregnancy reaching between 23 and 32 millimeters per hour in the ninth month and followed by a very gradual return to the upper

normal limits approximately 6 weeks post partum. Yet Titus warns that the finding of a rapid blood sedimentation rate indicates infection, and in a pregnant woman this is a particularly serious matter. He feels that it is safer, therefore to operate early in the presence of marked acceleration of the blood sedimentation rate.

During the first trimester of pregnancy the most common complications involving differential diagnosis with acute appendicitis are ectopic fallopian tubal pregnancy, salpingitis, early abortion, tumors of the right ovary. During the second trimester there are added right-sided nephritis, hydronephrosis, pyelitis, hydronephrosis, nephrolithiasis or ureterolithiasis, mesenteric lymphadenitis, mesenteric thrombi, intestinal obstruction, ileus duodenal and gastric ulcers, cholecystitis, and cholelithiasis. During the last trimester additional consideration must be given to premature labor, placenta previa, abruptio placentae, eclampsia and the complications of the toxemias. In the puerperium it is difficult to differentiate between the expected

after pains, parametritis, subinvolution of the uterus, cystitis, pyelitis, and the signs of acute appendicitis. Generally speaking the differential diagnosis between acute appendicitis and uterine fibroids as well as "red" degeneration of the uterine fibroids presents little or no difficulty.

McDonald reports an incidence of abortion in those cases of pregnancy complicated by appendicitis as follows: If the disease be limited to the appendix, the rate is 11.4 per cent; if an abscess be formed, the rate is 66 per cent; and in the presence of generalized peritonitis, the rate is 72 per cent. Jerlov, reporting on cases in Scandinavian hospitals, found the rate to be 13.8 per cent in the intrinsic disease, 55 per cent if an abscess had formed, and 63 per cent in the presence of generalized peritonitis.

McDonald reports a maternal mortality rate of 0.71 per cent when disease is limited to the appendix, 23.5 per cent when an abscess is present, and 30 per cent when peritonitis develops. The maternal mortality rates are the highest in patients who abort. Stoekel and Greenhill have estimated this mortality rate

at approximately 25 per cent during the last trimester of pregnancy labor and the puerperium. After rupture of the appendix, the maternal mortality rate is quoted by most authors at 50 per cent. Greenhill notes that 50 per cent of the patients abort following perforation of the appendix, and this increases the maternal mortality rate by 5 per cent. Maes and Boyce both emphasize that patients abort because they are dying; they do not die because they have aborted. Irving reported the maternal mortality rate at Boston Lying In Hospital as 11.8 per cent, and stated that 23.5 per cent either abort or have premature labor following appendectomy.

During the first 7 months of pregnancy early diagnosis and immediate appendectomy are considered the optimum in the surgical treatment of this problem. The uterus should be manipulated as little as possible during operation and postoperatively every effort should be exerted to prevent premature labor and abortion.

The therapy, treatment, and type of surgical and obstetrical procedure during the last trimester of pregnancy and labor have been the subject of considerable divergence of opinion. For this reason several of the proposed methods of surgical and obstetrical treatment of this problem as well as the date of publication are presented so that a fair evaluation may be made in the light of the most recent advancements in surgical procedures, postoperative care, chemotherapy and antibiotic therapy.

Mundé in 1894, stated "I would open the abscess at once, as soon as a reasonable probability of its existence could be settled, without reference to the pregnancy or the impending or complete delivery. I would prefer to take chances of puerperal infection from the abscess than of its unexpected rupture at any moment into the peritoneal cavity."

Cocke and Mason in 1920 said "If appendicitis occurs in the last month of pregnancy termination of the labor and the removal of the appendix are indicated. If the patient is a primipara, or if there is any doubt about immediate delivery in the multipara, cesarean section followed by appendectomy should be performed."

Wilson in 1927 stated, "If perforation and peritonitis are not present, then remove the appendix and leave the pregnancy alone. In the presence of marked peritonitis, a rapid Porro section is the safest procedure, and the low transverse section ranks next in safety; the classical section will not yield good results when performed in the presence of severe infection. To prevent the development of fetal toxicity, the displacement of surgical drains, the tearing of adhesions, and the spread of peritonitis during labor, cesarean section followed by appendectomy is advocated as the procedure which will give the best results."

McDonald in 1929 in a multipara at term and in labor manually dilated the cervix under ethylene anesthetic, performed a podalic version and extraction and then a laparotomy and appendectomy. Mother and child lived. He states "Cesarean section for cause other than obstetric should be avoided if a more conservative method of delivery is available."

Stander in 1936 said "It is suggested that the uterus be emptied by cesarean section before attacking the appendix. We, however, do not believe that this is always necessary and are convinced that its general adoption will add to the gravity of the operation."

Cosgrove in 1938 stated "Acute appendicitis is a surgical condition calling for prompt operative intervention. Its surgical treatment should not be combined with any manipulation to terminate pregnancy. This statement may be modified only by the legitimacy of a simple procedure to expedite termination of the second stage of spontaneous labor and in the case of the recognition of the very rare possibility of concurrent serious factors of obstetrical dystocia, such interference should be reserved until after the onset of spontaneous labor and then an extraperitoneal approach selected."

Zander in 1942 said "The pregnant woman with acute appendicitis is first a surgical problem and second an obstetrical problem. Operation should be carried out without delay and delivery accomplished by natural channels at term unless an absolute indication is present demanding abdominal section. Porro section may be necessary if perforation or abscess formation has occurred."

TABLE I.—SUMMARY OF 26 CASES

	Hospital No.	Age	Parity	Gestation	WBC	Pathology report	Mortality	
							Mother	Child
	94-173	32 yrs.	1	7 wks.	1,300	Acute diffuse appendicitis	N	Abortion on 4th post operative day
	3-30	yrs.		6 wks.	13,400	Acute periappendicitis	No	Abortion
3	-203	30 yrs.	2	7 wks.	1,000	Acute catarrhal appendicitis	No	Abortion

	148-45	23 yrs.	3 mos.	16,850	Acute appendicitis (suppurative) with fecolith	No	N	
13	05-73	20 yrs.	3 mos.	6,700	Acute suppurative appendicitis	No	No	
13	27	3 yrs.	3 mos.	20,600	Acute suppurative appendicitis	N	N	
4	244-900	23 yrs.	3	3 mos.	6,300	Acute suppurative appendicitis	N	N
5	55-283	yrs.	1 1/2 mos.	13,450	Acute suppurative appendicitis	N	N	
16	74-137	yrs.	2	4 mos.	5,000	Fibrous involution of appendix	N	N
17	70-100	24 yrs.		4 mos.	8,700	Fibrous obliteration of tip of appendix	N	N
8	76-026	24 yrs.	2	4 mos.	13,700	Acute appendicitis with fecolith	No	N
9	144-101	3 yrs.		5 mos.	1,450	Acute catarrhal appendicitis	N	N
20	8-067	24 yrs.	1	5 mos.	2,800	Acute and chronic granulomatous inflammation of large bowel consistent with clinical diagnosis of periappendiceal abscess (3 yrs. p. o. pelvic) was operated on for partial intestinal obstruction which proved to be caused by large mucous adenocarcinoma of the cecum	N	Spontaneous delivery of macerated fetus on 16th postoperative day
	8-187	24 yrs.		4 mos.	6,100	Acute diffuse appendicitis	No	N
23	61-280	33 yrs.	0	6 1/2 mos.	7,000	Acute suppurative appendicitis	Died on 3rd post operative day	Spontaneous delivery of stillborn on 2nd postoperative day
3	27-450	34 yrs.		7 mos.	27,000	Acute gangrenous appendicitis with rupture	No	Spontaneous delivery of living female on 1st post operative day Wt. 855 gms died 4 hrs. after delivery
24	203-909	3 yrs.	3	9 mos.	5,000	Acute suppurative appendicitis	Died on 2nd post operative day	Spontaneous delivery living male child. Wt. 3,300 gms died 7 mos. of age
3	71-233	27 yrs.		9 mos.	1,300	Acute suppurative appendicitis	N	Cesarean delivery of living male child. Wt. 3,300 gms.
20	54-243	23 yrs.		9 months	1,500	Appendiceal abscess, retroperitoneal	No	Spontaneous delivery living female child

Case 22. Thirty hours postoperatively patient went into labor within 1 hour spontaneous delivery of stillborn. Retained placenta with post partum hemorrhage.

Case 24. Labor developed postoperatively and within 1 hour premature separation of the placenta, followed by aspiration pneumonia developed during anesthetic.

Case 5. Patient entered the hospital in labor. Transverse isoperitoneal type of cesarean section.

Case 26. Symptoms of acute appendicitis and rupture developed 6 hours postpartum. Appendiceal abscess drained on 2d postpartum day.

TABLE II—SUMMATION OF APPENDECTOMIES AND DELIVERIES AT THE UNIVERSITY HOSPITALS OF CLEVELAND 1934-1946 INCLUSIVE

Total number of deliveries	49,683
Hospital deliveries, private and staff	32,968
Home deliveries	16,715
Total number of appendectomies	9,752
Number of appendectomies performed	
males between the ages of 12 and 50 years	4,330
Total number of acute appendicitis cases	2,434
Number of acute appendicitis cases in females between the ages of 12 and 50 years	822
Total number of acute appendices with rupture	45
Number of acute appendices with rupture in females between the ages of 12 and 50 years	68
Total number of appendiceal abscesses	76
Number of appendiceal abscesses in females between the ages of 12 and 50 years	38

W Stoeckel in 1943 stated: "In the presence of peritonitis or possible abscess, the uterus must be emptied; the method of choice is for one operator to perform the appendectomy and a second operator to perform a vaginal hysterotomy following the emptying of the uterus the surgical drains can be placed in the abdominal incision and the latter closed and then the vagina repaired."

Greenhill in 1945 said: "In consideration of the high mortality of suppurative peritonitis at or near term, perhaps it is best in the interests of the two individuals, to do an appendectomy followed by a Porro section; the classic cesarean section is contraindicated; laparotrachelotomy is safer but the extra peritoneal section is still better."

Te Linde in 1946 said: "When dealing with an acutely inflamed appendix during pregnancy regardless of stage, the removal of the appendix with the least possible amount of surgery is the safest and the chances for spread of the infection are minimized. When there is evidence of peritonitis, five grams of sulfanilamide may be profitably left in the peritoneal cavity."

For the purpose of studying further this complex surgery and obstetrical problem, the records of the obstetrical gynecological and surgical services of the University Hospitals of Cleveland were reviewed for the 13 year period, 1934 to 1946 inclusive. Inasmuch as the obstetrical service maintains an in-home delivery service as a part of the outpatient service in connection with the depart-

TABLE III.—SUMMATION OF ABDOMINAL DISEASE COMPLICATIONS OF PREGNANCY, LABOR AND THE PUERPERIUM—THE UNIVERSITY HOSPITALS OF CLEVELAND 1934-1946 INCLUSIVE

Disease	Number of cases
Acute appendicitis	26
Ectopic fallopian tube pregnancy	21
Ovarian tumors or cysts	46
Cholecystitis	26
Acute salpingitis	9
Hydrophorosis	
Urolithiasis	

ment of obstetrics of the Western Reserve University School of Medicine, the home deliveries are included for this same period of time. It is the practice of this service to admit to either The University Hospitals or The Cleveland City Hospital all patients developing complications requiring hospitalization during the pregnancy, labor or puerperium. Hence, the records of Cleveland City Hospital were reviewed to assure no mistake in our series. No cases of appendicitis complicating pregnancy, labor or the puerperium which had been referred from the distinct home delivery service could be found in our records.

Table I presents in brief a summary of 26 cases of appendicitis complicating pregnancy, labor or the puerperium which have occurred in this 13 year period at The University Hospitals of Cleveland. Cases 22 and 24 are illustrative of the fatal type of postoperative complications which may develop during labor and delivery following appendectomy. The high leucocytosis range in almost every case is of particular interest. Cases 7 and 30 bespeak of the more rare complications which may be encountered. In this series, 84 per cent of the patients developed acute appendicitis during the first 6 months of gestation. The abortion rate was 26.1 per cent, the fetal and neonatal mortality rate (including abortions) was 34.6 per cent, and the maternal mortality rate 7.69 per cent.

Table II presents a summation of the total number of deliveries and the total number of appendectomies during this same 13 year period at the University Hospitals of Cleveland. In this 13 year period there was an incident rate of appendicitis complicating pregnancy, labor or the puerperium of 1 to 1,010

deliveries. An incident rate of pregnancy associated with acute appendicitis in females within the childbearing age of 1 to 31 was found.

Table III presents a summation of the abdominal disease complications of pregnancy which required hospitalization or surgery during this same 13 year period at The University Hospitals of Cleveland. Uterine fibroids have been omitted because it was not considered that they produce a syndrome which might readily be confused with acute appendicitis.

Table IV is a review of a large number of the reported cases found in literature. Jerlov's series is omitted because it is understood to be included in Heineck's series. We make no apologies for the completeness of this series for the problem of reviewing medical literature on this subject is one of considerable proportions. This series is presented primarily to emphasize the rarity in which acute appendicitis occurs as a complication of labor or the puerperium.

Within the past several months, 1 case with appendicitis complicating term labor and 1 case with appendicitis complicating the puerperium have been seen on the Obstetrical Service of University Hospitals of Cleveland. They are cases 25 and 26 in Table I. In discussing these 2 cases with our Cleveland colleagues, it was learned that 2 cases of acute appendicitis complicating the puerperium had been seen during the past year at St. Ann's Maternity Hospital of Cleveland. Through the courtesy of Dr. Edward J. Keefe and the late Dr. Ralph B. Thompson the clinical histories of these 2 cases as well as the clinical histories of the 2 cases from our own service are presented.

CASE 1 (Case 25 in Table I). B. Z. Hosp. No. 71-232. Private patient of Dr. Folger. The patient was a 27 year old white female, secundipara admitted to the Obstetrical Service of University Hospitals on September 5, 1946. She was first seen by the attending obstetrician during the third month of gestation. At this time the hemoglobin was 50 per cent, blood pressure 100/50, serology negative. Pelvic measurements were within normal limits. Previous labor was normal, and the child weighed 6 pounds, 14 ounces at birth. Present antenatal course was uneventful until the

sixth month of gestation at which time she had one episode of acute lower abdominal pain. Bed rest and sulfadiazine therapy resulted in complete recovery. Thirty-six hours prior to admission patient had sudden recurrence of lower abdominal pain radiating to the lumbar region and associated with nausea and vomiting. Sedation relieved these symptoms. On admission to the hospital this patient was apprehensive and in apparent acute distress. She complained of severe abdominal pain accompanied by nausea and vomiting of less than 2 hours duration. Examination revealed no abnormalities of the abdomen. Examination revealed no abnormalities of the cardiovascular or respiratory systems. The abdomen protruded with the tumor of pregnancy extending to 8 centimeters below the xiphoid process. The anterior abdominal wall was tense and tender to palpation. The rectus muscles were not rigid. There were irregular uterine contractions lasting 50 seconds and occurring at intervals of 3 to 6 minutes. Rectal examination revealed the cervix to be patulous and dilated from 1.5 to 2 centimeters. No acute tenderness was noted on tensing the rectal walls. There was no vaginal discharge. The renal areas were nega-

tive. Hemoglobin was 88 per cent, white blood cells 22,650 urine essentially negative temperature 38 degrees blood pressure 100/50 pulse 100 respirations 24 fetal heart rate, 140 in right lower quadrant. Following sedation with demerol 100 milligrams intramuscularly patient received some relief. During the next 6 hours she was observed. The uterus remained tense, the abdominal pain was more pronounced on the left lateral wall but the entire abdomen was acutely tender to all palpation. Consultation was held and a tentative diagnosis of placental separation with retroplacental hematoma and intrauterine hemorrhage was made. A secondary diagnosis of twisted gangrenous ovarian cyst was considered. The fetal heart at this time was very rapid. Cesarean section was immediately performed.

When the abdomen was opened through a low midline incision purulent exudate was encountered. Transverse laparotrachelotomy was performed. A living female infant weighing 3120 grams was delivered. The placenta and membranes were not remarkable. The myometrium was closed in layers. The uterovesical peritoneal fold was imbricated and advanced 3 centimeters in covering the uterine incision. The uterus was then delivered through the abdominal incision. Appendectomy was performed and the stump was ligated but not inverted. Ten grams of sulfathiazole crystals were placed in the peritoneal cavity. The abdominal wall was then closed in layers and the skin was closed with clips.

Postoperatively the patient was given 100,000 units of penicillin intramuscularly every 4 hours for 7 doses following which she received 20 doses of 50,000 units each intramuscularly, a total of 1,700,000 units of penicillin. A Levine tube was passed into the stomach immediately after operation and gastric suction was maintained for 72 hours. She received 250 cubic centimeters of whole blood following which she had a mild thermal type reaction. Glucose and saline intravenous solutions were given for 48 hours. On the third postoperative day she was afebrile and was given a liquid diet. On the fourth postoperative day she was given a soft diet followed by a regular house diet. She remained afebrile. On the fifth postoperative day the white blood count was 20,500. The patient was discharged on the tenth postoperative day, both she and the baby were in good condition. Pathologist's report: "Acute suppurative appendicitis."

CASE 2 (Case 26 in Table I) M. B. Hoep No. 254 243 Staff Service.

The patient was a 32 year old white female, secundipara, admitted to the Surgical Service of University Hospitals June 9, 1946. She was not attended by a physician during her antenatal course of during labor. Following delivery of a living female child weighing 7 pounds, 8 ounces she requested medical attention. The externs answering this request expressed the placenta and membranes without difficulty. She was given ergotrate, 1/320 grain by mouth. Temperature was 37.4 degrees

blood pressure, 110/65 pulse, 98. Labor was estimated at 10 hours according to the patient's story. It was not remarkable. For afterpain, the patient received 4 doses of paregoric, 1 teaspoonful at 3 hour intervals.

Approximately 6 hours postpartum, the patient experienced shaking chills accompanied by sharp pain in the right flank radiating to the right costovertebral angle. The patient was visited at the time by one of the obstetrical residents. Temperature was 39.5 degrees. Examination revealed diminished breath sounds over the right chest. The abdomen was markedly distended no rebound tenderness there was a visible bulging of the right abdominal wall over the crest of the ilium. The patient was sent immediately to the hospital and admitted on the Surgical Service with a tentative primary diagnosis of paraneuritic abscess on the right, and a secondary diagnosis of possible acute appendicitis with perforation and peritonitis.

Hemoglobin was 80 per cent, white blood cells 12,500. The urine showed traces of albumen, 10 to 15 red blood corpuscles per highpowered field, and 5 to 10 white blood cells per highpowered field. X-ray film of the chest was negative. Retrograde pyelograms revealed moderate hydronephrosis and dilatation of the right ureter. She was observed for 30 hours, following which she was taken to surgery and a retroperitoneal abscess of the right lateral abdominal wall drained of 500 cubic centimeters of thick, purulent exudate. The abscess cavity was irrigated with normal saline and at its base the cecum and the edematous appendix could be visualized. The peritoneum was not entered. The cavity was loosely packed and a large cigarette drain was inserted. Postoperatively she received intravenous sulfadiazine and 30,000 units of penicillin intramuscularly every 3 hours. After the first day sulfadiazine therapy was given by mouth. The sulfadiazine therapy was continued until her eighth postoperative day, and the penicillin until her twelfth postoperative day. Hot abdominal stupes were used for 10 days.

The temperature ranged from 39.5 degrees the first 24 hours postoperatively to 37.5 degrees on the sixth postoperative day. She remained afebrile the remainder of her hospital stay. Sulfadiazine level on the first postoperative day was 10.4 milligrams and on the eighth postoperative day 14.4 milligrams. Blood urea nitrogen on the second postoperative day was 10.5 blood chlorides, 98.8 serum protein, 6.5. Urine culture showed hemolytic *Staphylococcus aureus*. Abscess culture showed *Bacillus coli*, *Staphylococcus aerogenes*.

The patient was ambulatory on the seventeenth postoperative day and discharged on the twenty-first postoperative day. Two months after operation the abscess wound was completely granulated and there was no drainage. She was advised to return in 4 months for an elective appendectomy. Roentgenogram showed marked reduction in the size of the right hydronephrosis.

CASE 3. G. C. Hosp No C-893 Staff patient at St. Ann's Maternity Hospital

This patient was a 31 year old white female quadripara, admitted to St. Ann's Maternity Hospital July 23 1946. Previous pregnancies and labors were uncomplicated three living children. She attended the obstetrical out patient department at St. Ann's Hospital beginning in the fourth month of this gestation. During the sixth month of pregnancy, she was admitted to the hospital complaining of vague right upper quadrant abdominal pain no nausea or vomiting, no temperature elevation. Following 36 hours of bed rest patient was discharged. The patient entered the hospital at term, with labor well established. Physical examination was essentially negative. She received demerol and scopolamine analgesia during the first stage of labor which lasted 8 hours and 15 minutes. Second stage was of 55 minutes duration. Patient was given nitrous oxide oxygen and ether and delivery was by means of outlet forceps. Placenta and membranes were delivered complete. Third stage duration was 5 minutes. Patient received ergotrate 1/320 grain intravenously and then three times a day for 3 days. On the first postpartum day the patient developed abdominal distention with temperature elevation of 38 degrees. She complained of generalized abdominal pain. The white blood cells numbered 15,000. Hemoglobin was 80 per cent. Enema was given with no return. Later in the day there was one semimucous bowel movement. On the second day she developed nausea and vomiting continued abdominal distention, and temperature of 39.3 degrees. She was expelling flatus and passing loose stools. Enema was given but brought no return. One ampul of prostigmine was given every 4 hours for 6 doses rectal tube *ad libitum* penicillin 100,000 units initially followed by 30,000 units every 3 hours 4 times. Intravenous fluids were administered. On third postpartum day gastric suction was started. Penicillin and prostigmine were continued. Two enemas were given, with good results. The white blood count was 8,700 temperature dropped to 38.2 degrees. Fourth postpartum day abdomen was soft. Gastric suction and penicillin therapy were discontinued no vomiting liquid stool. Tenderness was present over the left lower quadrant and umbilicus. During the night of this day abdominal distention developed with pain in the right lower quadrant and epigastrium. Gastric suction was started again. On the morning of the fifth day the patient had a chill, skin became cold and clammy pulse 130, blood pressure, 90/55 temperature 40.1. Penicillin was restarted at 50,000 units intramuscularly every 3 hours. White blood cells numbered 11,000. Blood plasma and intravenous glucose were given. Patient lapsed into unconsciousness and her condition became progressively worse her temperature reaching 42 degrees. She died approximately 18 hours after shock had first occurred.

Pathologist's report—autopsy findings acute gangrenous inflammation of the appendix with per

foration and fecalith acute diffuse nephrosis diffuse acute fibrinopurulent peritonitis (1000 c.c.) cloudy swelling of the liver and adrenals corpus luteum cyst of left ovary, acute inflammation and necrosis of decidua acute hypertrophy of the uterus (recent pregnancy), acute hyperplasia of the spleen.

CASE 4. K. F. Hosp No 45-8309, Huron Road Hospital private patient of Dr. E. J. Keefe

This was a 23 year old white primipara. First prenatal visit was in the second month of gestation. She had a uniformly contracted pelvis—bispinal diameter 21 centimeters bicrestal, 26.5 centimeters external conjugate 18 diagonal conjugate 10.5 centimeters blood pressure 110/70 urinary, essentially negative serology negative. Physical examination revealed nothing remarkable. Antenatal course complicated by nausea and vomiting during the first 6 months of pregnancy was relieved by vitamin B therapy and sedation. X ray pelvimetry during the fortieth week of gestation revealed marked cephalopelvic disproportion with the fetal head not engaged. Elective cesarean section was performed at St. Ann's Maternity Hospital on October 4, 1945. Low cervical type under nitrous oxide oxygen and ether anesthesia. The uterus was closed in layers, also the abdomen. A living male child was delivered. Placenta and membranes were removed complete. The postoperative course was without incidence until the eighth postoperative day. At this time the patient noted general epigastric discomfort, nausea, but no vomiting. Temperature elevation was 38.2 degrees. No relief came from an enema and the use of sedation. On the ninth postpartum day there was slight abdominal distention, abdominal pain was localized in the right lower quadrant with marked rebound tenderness. Temperature was 38.5 to 38.7 degrees. Rectal examination revealed extreme tenderness in the right iliac fossa. Uterus was well involuted lochia normal. The abdominal wound was healing by first intention with no drainage and no tenderness (sutures were removed on the seventh postpartum day). White blood cells numbered 18,000 to 20,000 urine was negative. A diagnosis was made of acute appendicitis and the patient was transferred to the surgical service of Huron Road Hospital. Laparotomy was immediately performed under spinal anesthesia and cyclopropane. When the abdomen was opened through a right rectus incision profuse thin, purulent exudate was encountered. The appendix was inflamed and swollen, covered by fibrinous exudate and located retroperitoneally. Appendectomy was performed the stump was not inverted. Ten grams of sulfathiazole crystals were distributed in the peritoneal cavity. The uterine incision was walled off by the omentum and this was not disturbed. One large cigarette type drain was placed at the base of the cecum and the abdomen was closed in layers. After operation the patient received 500 cubic centimeters of whole blood 20,000 units of penicillin every 3 hours for 4 days and continuous hot abdominal stapes for 4 days. After the first post

operative day she was afebrile. The drain was removed on the fourth postoperative day. Sutures were removed on the seventh postoperative day and the patient was ambulatory on her eighth postoperative day. She was discharged on the ninth postoperative day. Pathologist's report "Acute suppurative appendicitis."

It is indeed a coincidence that these 4 cases of this serious surgical and obstetrical problem occurred here in Cleveland within the past year. Each case presents a different phase of the masked diagnostic clinical signs and symptoms. These 4 case histories warrant presentation if for no other reason than to emphasize the great difficulty encountered in making an early correct diagnosis of acute appendicitis. Case history 3 reveals the serious consequences of the delayed diagnosis followed by inadequate chemotherapy or antibiotic treatment and insufficient gastrointestinal decompression. The use of enemas and prostigmine must be attributed to the incorrect diagnosis. Cases 1, 3, and 4 present the satisfactory results following correct early diagnosis properly executed surgical procedures, adequate intravenous nutrition, maintenance of gastrointestinal decompression and sufficiently prolonged administration of chemotherapy and antibiotic therapy.

DISCUSSION

If this complicated surgical and obstetrical problem is considered as a pathological condition involving the appendix and a physiological condition involving the pregnancy then it behooves us to find the best remedy to obliterate the pathological condition. One is impressed by the geometrical rise in the mortality rates to both mother and child in the presence of peritonitis.

The optimum of treatment during the first 7½ months of pregnancy is as stated above, a well timed and properly executed appendectomy with the least possible manipulation of the uterus, gastrointestinal decompression, blood plasma, and fluids intravenously and adequate chemotherapy and antibiotic therapy. Postoperatively some authors report good results from the intravenous administration of estrogen-progesterone therapy to avoid abortion or premature labor.

The difficult problem then occurs in the treatment of the patient during the last 2½ months of pregnancy, labor and the puerperium, particularly if perforation of the appendix has taken place followed by diffuse peritonitis.

Meyer, Requarth, and Kosoff found that the lowered mortality rate at Cook County Hospital for acute appendicitis with perforation and peritonitis is chiefly attributed to the use of chemotherapy. They have demonstrated that this rate was reduced from 26.4 per cent (1928-1938) to 13.9 per cent (1941-1945). These same authors report that appendectomy with drainage is associated with the highest mortality rates. Hoerr, in reviewing the fatalities in operative appendicitis between 1913 and 1940 at the Peter Bent Brigham Hospital, found delay in operation the major factor in cause of mortality. He also states that closure without drainage is indicated in his study. Waugh, McCall, and Herrell at the Mayo Clinic found no marked difference in the relative efficacy of sulfanilamide and sulfathiazole used intraperitoneally in perforated appendicitis. They state that following implantation of either sulfanilamide or sulfathiazole intraperitoneally supplemented intravenous, oral or subcutaneous chemotherapy should not be started until after the second or third postoperative day and then may be continued for 5 days or longer if necessary. It is of note that they found high concentrations of sulfanilamide (ranging from 22 mgm. to 1,330 mgm. per 100 c.c. of peritoneal fluid) persisted at the site of the deposit in the peritoneal cavity for longer than 24 hours. They reported that the intraperitoneal use of sulfathiazole and sulfanilamide was the chief factor in reducing the mortality rate of perforating appendicitis from 16.9 to 3.8 per cent at the Mayo Clinic between 1926 and 1942.

Crile a recent report of 50 patients with proved appendiceal peritonitis successfully treated by the administration of 100,000 units of penicillin at 2 hour intervals for several days, commends the use of these large doses of penicillin in the presence of peritonitis. (He suggests that the large doses of penicillin are necessary to combat the action of the Eichen-

hina coli which is known to have an inactivating effect on penicillin)

Woltz and Zintel found no evidence of penicillin toxicity to either mother or child when penicillin was administered to the pregnant patient. Adequate penicillin levels were produced in both maternal and fetal circulation and in the amniotic fluid. Eastman in commenting on this study suggests the value of penicillin therapy in treating intrapartum infection and as a prophylaxis against intrauterine infection.

Tenney in commenting on the causes of maternal deaths in obstetrics, reports that sepsis still continues in 1946 to be one of the most important causes. He states that the treatment of sepsis resolves itself into the primary factors of blood transfusions fluids nutrition rest and chemo-antibiotic therapy.

How similar this recommendation is to 4 major contributions in the field of surgery of the past 2 decades which are applicable in the modern treatment of acute appendicitis and peritonitis (1) gastrointestinal decompression (2) intravenous nutrition (3) plasma and whole blood transfusions, (4) chemotherapy and antibiotic therapy.

The small number of cases reported in this paper warrants conservatism in recommending the method of choice in treating this surgical and obstetrical complication. It is to be recalled that acute appendicitis complicating the last trimester of pregnancy labor and the puerperium is rare hence anyone observer is hardly justified in generalizations with regard to therapy. The existence of the promising new therapeutic weapons of chemotherapy and antibiotic agents must not blind us to the importance of the many other factors involved in the proper care of the patient with acute appendicitis. In the hope of diminishing the maternal and infant (toxic) complications and maternal and fetal mortality rates the following suggested treatment warrants consideration by obstetricians gynecologists and surgeons confronted with a patient with acute appendicitis with or without perforation complicating the last 2 months of pregnancy or labor. Cesarean section by low transverse laparotomectomy followed by properly executed appendectomy intraperitoneal

implantation of 5 to 10 grams of sulfanilamide or sulfathiazole crystals massive doses of penicillin postoperatively for several days accompanied by gastrointestinal decompression, blood and plasma transfusions, and intravenous nutrition. It is to be remembered that appendectomy is performed not to treat appendicitis but to prevent peritonitis. Cesarean section in these cases provided the maximum opportunity for both mother and child to survive what may otherwise prove to be fatal postoperative complications such as adhesions disrupted surgical incisions, and intestinal obstructions with their accompanying peritonitis.

SUMMARY

1 A brief summary is presented keynoting the problem involved in making the diagnosis of acute appendicitis complicating pregnancy labor and puerperium.

2 A 13 year (1934-1946 inclusive) statistical summary of the records of the obstetrical summary of the records of the obstetrical gynecological and surgical services of University Hospitals of Cleveland, showing the incidence of abdominal disease complications of pregnancy, is presented in 3 tables. A fourth table presents the work of other authors in statistical form to emphasize the rarity of acute appendicitis complicating labor or the puerperium.

3 Four case histories of patients with acute appendicitis complicating labor or the puerperium which occurred in Cleveland during 1945 to 1946 are presented.

4 The efficacy of the use of chemotherapy and antibiotic therapy in the treatment of appendicitis and peritonitis is discussed.

5 No absolute conclusion is presented as to the optimum in the surgical and obstetrical treatment of the patient presenting acute appendicitis as a complication of pregnancy labor or the puerperium. The method which was followed in our recent cases when combined with the experience of others in the use of the modern methods of surgery and postoperative therapy and care may serve as a basis to reduce the maternal and fetal complications, and to decrease the maternal fetal and neonatal mortality rates in this serious surgical and obstetrical problem.

PROGRESS IN THE SURGICAL MANAGEMENT OF DIVERTICULITIS OF THE SIGMOID COLON

JOHN deJ PEMBERTON M.D., B MARDEN BLACK M.D., and
CHARLES R. MAINO M.D., Rochester Minnesota

SINCE the turn of the century when the clinical significance of diverticula of the colon first came into prominence through the writings of Graser Fischer Beer Mayo Wilson and Giffin Moynihan Telling and others many valuable contributions to knowledge of the subject have been made by a host of workers (2 6 8 11 14 16 20 22-24 26) The literature is now voluminous, dealing with nearly every phase of the subject, such as the incidence, etiology and recognition of diverticulosis and the symptomatology classification recognition and management of the secondary pathologic changes that is diverticulitis and its sequelae Knowledge derived from these studies is widespread so that the value of further discussion of the subject would appear to be limited to emphasis and appraisal of established facts were it not that in recent years surgery of the colon has made momentous progress In view of these advances, re-evaluation of the surgical management of diverticulitis of the sigmoid seems definitely indicated to determine if the practice and teachings of former years are still valid

Surgery in the management of diverticulitis is limited largely to the treatment of certain complications notably perforation obstruction and fistula Brown wrote There should be a determined effort to avoid operation but he pointed out that it was both futile and dangerous to persist in a medical regimen after development of the complications just mentioned In addition to these classical indications for operation it is frequently impossible to exclude carcinoma on clinical grounds and exploration for this reason often is justified There is lack of agreement as to what

should be done surgically in the management of complicated diverticulitis, particularly as to the necessity of resection in many cases. Since the literature contains no report of a series of cases of diverticulitis in which surgical treatment has been carried out in conjunction with modern chemotherapy the present study therefore was undertaken with a twofold purpose in mind (1) to appraise the different surgical procedures in the management of diverticulitis of the sigmoid and (2) to determine what effect the application of modern chemotherapy has had on the immediate mortality

Records were available of 389 patients' whose diverticulitis involved the sigmoid only or the sigmoid together with a portion of the descending colon, and who were treated surgically For the purpose of this study the patients were divided into two series namely series A which comprised 245 patients treated surgically in the years 1908 to 1940 inclusive and series B which comprised 144 patients operated on in the years 1941 to 1945 inclusive. The data relating to incidence and symptomatology of the disease cited were derived from the records of the latter series (B) whereas the data relating to late results of treatment were obtained primarily from the earlier series (A) The surgical mortality rate of each series was computed.

It is estimated that in excess of 5 per cent of all individuals more than 40 years of age have diverticulosis of the colon but the condition is rare among persons less than this age Of more than 47,000 roentgenologic examinations of the colon made at the Mayo Clinic in the pe-

Patients whose diverticulitis was discovered by operation directed primarily at treatment of some other lesion, and who were not treated surgically for the diverticulitis, were not included in this series. Five patients have been included two times in this series. In each case, the patients were treated surgically for diverticulitis, the disease recurred and another series of operations was carried out. There were actually 384 individuals in the series.

SURGERY GYNECOLOGY AND OBSTETRICS

TABLE 1.—SYMPTOMS AND SIGNS OF DIVERTICULITIS OF SIGMOID IN 144 CASES IN WHICH OPERATIONS WERE PERFORMED—SERIES B

Symptoms or signs	Cases	Per cent of 144
Evidence of inflammation	14	79
Complete or partial lateral obstruction	48	30
Diarrhea	27	9
Mucus in feces		6
Blood in stool	5	8
Mass		20
Abdominal		
Pelvic	2	40
Flank	12	
Sigmoidal carcinoma		
Sigmoidoventral		
Sigmoidoenteric		
Multiple	7	
Other type	1	

More than one symptom or sign occurred in each of many cases.

from 1941 to 1945 inclusive, diverticulosis was discovered in 8.5 per cent. It is not known in what proportion of patients with diverticulosis symptoms attributable to inflammatory changes in the diverticula will develop but Abell has estimated that 10 to 20 per cent, and Brown and Marckley that 12 to 16 per cent of patients with diverticulosis ultimately will have diverticulitis. In the same period (1941 to 1945 inclusive) the diagnosis of diverticulitis of the sigmoid was made in 600 cases which represent 15 per cent of the cases of which treatment was employed. Thus it can be estimated that in about 1 out of every 4 patients with diverticulitis complications requiring surgery will develop.

The age and sex distribution of patients in series B was in keeping with those of patients reported by others. The youngest male in the series was 29 years, and the youngest female 33 years of age; the oldest male was 80 years and the oldest female 79 years of age, while the mean age was 53.6 years at the time of the operation. The ratio of males to females was 2 to 1.

Since diverticulitis may be severe from the onset of symptoms it is not surprising that many patients required operation relatively

soon after their first symptoms were noticed. In series B 12 per cent of the patients were operated on within 1 month and 31 per cent within 6 months of the onset of the disease. It is of some interest that a greater proportion of patients in the older age groups were operated on sooner after the onset of symptoms than were the younger patients. Thus, of the patients in their forties or less, 19 per cent were operated on within 6 months of the first symptoms; of those in their fifties, 29 per cent, and of those in their sixties or more, 38 per cent.

The symptoms which the patients in series B presented are shown in Table I. Such symptoms and signs as tenderness, fever and leucocytosis have been grouped under the broad heading of inflammation. Many patients presented several of the symptoms listed. On physical examination 36 per cent had a mass which could be palpated beneath the abdominal wall or through the rectum and 41 per cent had a fistula which had followed former operative procedures or had developed spontaneously. Certain other signs, not covered in Table I, were significant and will be set forth here. Evidence revealed by sigmoidoscopic examination was of considerable value in the diagnosis. Of the 94 patients who were subjected to sigmoidoscopy findings suggestive of diverticulitis, such as unusual sacculization, angulation, fixation of the bowel, constriction of the lumen, edema of the mucous membrane or the presence of an extraluminal mass were recorded concerning 63 per cent, while one or more diverticula were visualized in examination of 14 per cent. Roentgenologic examination after barium enema was of the greatest aid in the diagnosis. This procedure was carried out on 104 patients. The diagnosis of diverticulitis, diverticulosis, or both was made in 66 per cent of this group, the diagnosis of an obstructing lesion in 22 per cent, and the diagnosis of a fistula of the sigmoid only was made in 8 per cent. Thus, in only 1 per cent did the roentgenologic examination fail to show any evidence of a lesion suggestive of diverticulitis or diverticulosis.

It is agreed generally that carcinoma is no more likely to develop in a segment of bowel

involved by diverticulitis or diverticulosis than it is in a segment of bowel not so involved. Furthermore the association of diverticulitis and carcinoma is not common. Rankin and Brown reported that in 227 cases of diverticulitis carcinoma was encountered in only 4 and that diverticulitis was present in only 4 of 679 cases of carcinoma. During the period 1941 to 1945 inclusive, 11 of the patients who were successfully operated on for carcinoma of the colon or rectum were found by the surgeon or pathologist to be suffering also from diverticulitis of the sigmoid. In 5 cases the carcinoma was situated in a segment of bowel distant from the diverticulitis. Since the operative procedure was primarily directed toward removal of the carcinoma in all of the cases, the inflammatory lesion was considered of secondary significance and this group of 11 cases was not included in the series of cases of diverticulitis.

While there is perhaps no causal relationship between diverticulitis and carcinoma, the clinical manifestations and gross appearance at operation of these two stenosing lesions are frequently indistinguishable one from the other as was first pointed out by Moynihan in 1907. In roughly 25 per cent of the cases in this series carcinoma could not be excluded by clinical methods of examination. Even at operation the surgeon was unable to differentiate between carcinoma and diverticulitis in many cases. The error was made both ways and several cases of what was mistakenly considered to be locally inoperable carcinoma were proved subsequently to be cases of stenosing diverticulitis. More frequently extensive resection was done to remove radically a supposedly malignant lesion either without preliminary colostomy or within a few weeks after the establishment of a colonic stoma. It was thought that for the patient's sake, sufficient time could not be allowed to elapse for the inflammatory reaction to subside. If the delay had been thought advisable, the inflammatory character of the lesion would have become evident.

SURGICAL TREATMENT OF DIVERTICULITIS

Various surgical procedures were employed to treat the patients in both series. The fac-

TABLE II.—DATA ON SURGICAL PROCEDURES PERFORMED IN THE CASES IN SERIES B PRIOR TO ADMISSION TO CLINIC

Previous operations	Cases	Finding on admission	Cases
Ileostomy (months previous)	1	Ileostomy	
Colostomy	10	Inadequate diversion	1

Colostomy and resection of sigmoid	42		
Total			

tors that influenced the choice of procedure employed were diverse. The most important of which were the presence or absence of obstruction, the acuteness of the process, the extent of the diverticulitis and of inflammation of the mesocolon, the presence or absence of fistula and the relative accessibility of the involved segment of the sigmoid. Patients treated surgically in essentially the same manner were grouped together and an attempt was made to evaluate the results following the different methods of surgical treatment both as to the immediate mortality and the ultimate outcome. It is evident that when the involved segment of bowel is not resected recurrence of the diverticulitis always remains a possibility.

The various surgical procedures to be discussed subsequently were all carried out at the Clinic. Many patients in both series had had previous operations, because of diverticulitis before they were first seen here. Since many such operations on patients in series A were of historic interest only they will not be mentioned. The previous operations on patients

carried out in 5 cases and in 3 cases, subsequent attempts to close the stoma had been made, all of which had failed.

A conception of the disability and the serious condition that may follow closure of a colonic stoma, made with adequate indication in treatment of complicated diverticulitis can be gained from review of the following case.

A physician, 47 years of age, had the first symptoms of diverticulitis 2 years before he was first seen at the clinic. At that time an exploratory operation had been done because of lower abdominal tenderness and pain. A pelvic abscess due to perforating diverticulitis was found and appendectomy was done. Following this operation a persistent external fecal fistula developed and the patient continued to have recurrent pelvic abscesses.

Approximately 2 years after this operation a double-barreled colonic stoma, orad to the diverticulum, was established at the clinic and the pelvic abscesses were drained. Complete relief from all symptoms followed and the patient insisted that the stoma be closed in spite of advice to the contrary. At his request, also, the ventral hernia that resulted from the original operation was repaired about 6 weeks after the closure. Less than 3 months later recurrence of the diverticulitis and development of another pelvic abscess necessitated the establishment of a second double-barreled colonic stoma. The patient was much relieved again but returned to the clinic 6 months later when at his insistence a second attempt was made to repair the ventral hernia. This operation was complicated by extensive infection of the body wall which required drainage on several occasions. Three and a half years after establishment of the first stoma, and approximately 1 year after establishment of the second stoma, the patient was persuaded to submit to resection of the involved segment of sigmoid. An exteriorization type of operation was done. The resulting temporary stoma and the previously established colonic stoma were closed successfully and without complications within 18 weeks of the exteriorization operation.

In all he was almost completely disabled for 6 years from the time of the first operation and he spent considerably more than half of this time in a hospital.

Resection of the involved segment of colon. The majority of patients in both series were subjected to some type of resection of the involved sigmoid. It is our feeling that when adequate indications exist for surgical interference, the safest procedure is to establish, orad to the lesion, a colonic stoma that completely diverts the fecal stream and then to allow sufficient time for the inflammatory

reaction in and around the walls of the sigmoid to subside before attempting further surgery. Whether or not subsidence has occurred can be judged from proctoscopic and roentgenologic examination but, as a rule, 6 months to 1 year should elapse before resection is undertaken. Obviously whenever serious suspicion of malignancy exists, the resection must be undertaken much earlier. The presence of extensive peridiverticulitis materially increases the risk of resection. From the present review it would seem, also, that exteriorization operations are safer than procedures in which primary anastomoses are attempted.

Preliminary colonic stoma, subsequent exteriorization operation.—In series A, 21 patients were treated by means of a preliminary colonic stoma and a subsequent exteriorization operation. There were 3 hospital deaths in the group, a mortality rate of 14 per cent for the resection. Of the remaining 19 patients, 16 are well. Of the 3 remaining patients of the 19, 1 has continued to complain of pain in the region of the exteriorization operation and 1 committed suicide 2 years after the operation, presumably because of ill health. The final patient of the 3 died elsewhere of what was reported to be obstruction of the bowel 1 year after the resection.

In series B 41 patients had an exteriorization type of resection following establishment of a colonic stoma. There were no deaths in this group.

Preliminary colonic stoma with subsequent end-to-end anastomosis.—In series A, 24 patients were treated by means of preliminary colonic stoma and subsequent resection with an end-to-end anastomosis. There were 4 deaths, a hospital mortality rate of 17 per cent for the resection. The colonic stomas of 3 patients who survived the operation were still open at the last report and 1 patient in the group has been lost track of. Fifteen of the 16 remaining patients are well and 1 patient has a persisting fecal fistula at the site of the resection but no other symptoms.

In series B this type of operative procedure was performed on 20 patients with 1 fatality.

Resection without preliminary colonic stoma.—There is a small group of cases of complicated diverticulitis in which it is relatively

safe to perform a primary resection and to unite the bowel by end-to-end anastomosis. The criteria of safety for such a procedure are (1) There should be no evidence of obstruction (2) The inflammatory process should be chronic or mildly subacute (3) The involved segment of the bowel should be short, so that after resection the two cut ends of the bowel which are to be united are free of inflammatory infiltration. Safety will be further assured if before closing the abdomen a temporary colonic stoma is established in a loop of bowel orad to the site of resection.

Primary resection of the involved segment of colon was carried out in 98 cases in series A. An exteriorization type of operation was done in 76 cases with 13 deaths in the hospital. Primary resection with end-to-end anastomosis was employed to treat 16 patients with 2 deaths in hospital and primary resection with side-to-side anastomosis was done in 2 cases without a fatality. In the 4 remaining cases, continuity of the bowel was not re-established and the patients were left with single-barreled colonic stomas. One of these patients died. The mortality rate of 16 per cent in these 98 cases compares favorably with the mortality rate of the two stage operation of preliminary colostomy and resection which was 15 per cent. It is probable however that patients treated by primary resection had no obstruction and less extensive and less complicated diverticulitis than did those treated by means of preliminary colostomy and subsequent resection.

As mentioned above, primary resection without anastomosis was attempted in 4 cases each of the patients was left with a single-barreled colonic stoma. The indication for this procedure usually was that the bowel was so shortened that neither an exteriorization operation nor primary anastomosis was thought feasible at the time of resection. One patient as has been said died following the operation; 1 patient subsequently underwent successful anastomosis between the sigmoid and the rectosigmoid and 2 patients remained well but with the colonic stoma.

Now to cast back a few sentences to primary exteriorization operations. Results were comparable to those following other types of

resection. Fifty of the 63 patients who survived the operation were entirely well and 9 others were well but had fecal fistulas at the site of the exteriorization. In 7 of these 9 cases one attempt at closure failed and in 2 of the 9 closure had not been attempted. Two patients of the 50 died of causes unrelated to their diverticulitis and 2 others complained of persisting pain in the region of the operative incision.

Fourteen patients survived the operation of primary resection with end-to-end anastomosis. Nine patients were well at the last report. Three had persisting fecal fistulas with attacks of inflammation. In 1 case of this group of 3 a colonic stoma was made subsequently and since then the patient has remained well with the stoma. In the remaining 2 cases of the 14 strictures of the bowel developed at the site of the anastomosis. The late results following this type of resection were less satisfactory than those following other types of resection.

In series B primary resection of the involved segment of sigmoid was carried out in 48 cases. An exteriorization type of resection was performed in 38 cases with 1 fatality. In 6 cases primary resection of the sigmoid with end-to-end anastomosis was performed and before closure of the abdomen a temporary colonic stoma was established in a loop of the patients survived. Primary resection with end-to-end anastomosis without colostomy was carried out in 4 cases with 1 fatality.

Other operative procedures. In series A other procedures were carried out rarely usually because of unusual circumstances. In 2 cases after preliminary colostomy the involved segment of colon was resected and the ends above and below the resected portion were turned in and dropped back into the abdomen. One of the 2 patients died of pulmonary embolism and the other remained well with the double-barreled stoma. Cecostomy in 2 cases ileocolostomy and appendicostomy in 1 case each were carried out for treatment of high grade obstruction. Three of the 4 patients died and the remaining patient recovered and required no further surgical treatment. Ileocolostomy was attempted in 3 cases with 1 death in hospital. One patient had recurrent partial ob-

TABLE III.—MISCELLANEOUS SURGICAL PROCEDURES CARRIED OUT AT MAYO CLINIC IN SOME OF THE CASES OF SERIES B

	Cases
Drainage of pelvic abscess	
Closure of colonic stomas Stomas established elsewhere	4
Stomas followed resection of sigmoid elsewhere	
Colostomy and closure of jejunoileal fistula	
Colostomy and repair of fistula	
Colostomy repair of fistula and closure of colonic stomas	
Colostomy resection of sigmoid, ileocecalostomy and partial colectomy	

struction and 1 a persistent fecal fistula after this procedure. In 2 cases the sigmoid was simply wrapped in omentum. One of these 2 patients continued to have recurring attacks of diverticulitis while the outcome in the other case is not known. In 3 cases, drainage of an abscess caused by diverticulitis was the only surgical procedure employed. The results in all 3 cases were poor. In 1 other case, the sigmoid was freed up and sutured to the body wall with no improvement in the symptoms.

Miscellaneous procedures which included resection and which were employed in series B are represented in Table III.

Mortality in series A and B compared. The surgical procedures employed and the mortality rates in the two series are shown in Table IV. In comparing the two series, the most noteworthy feature is the marked reduction in mortality rate in series B to 4.2 per cent together with a decided rise in the rate of resectability. Of the 245 patients in series A, resection of the involved segment of sigmoid was carried out in 146 or 60 per cent, whereas of the 144 patients in series B the bowel was resected in 111 or 77 per cent. The contrast between the two series is even more striking when the mortality rate in the cases in which resection was performed is compared. Of the 146 patients (8 from the miscellaneous group of Table IV) in series A who underwent resection 24 died in hospital a mortality rate of 16 per cent whereas of the 111 patients in series B who underwent resection 3 died, a mortality rate of 2.7 per cent.

TABLE IV.—SURGICAL PROCEDURES AND MORTALITY RATE

Surgical procedures	Series A: 1908-1940			Series B: 1941-1943		
	Patients	Deaths	Per cent	Patients	Deaths	Per cent

Miscellaneous	28	7	25.0	16	—	—
	178	26	14.6	144	3	2.1

As explained in the text (paragraph 2), there were actually 3 patients less than 144.

Of the 6 patients in series B who died, infection attributable to the operation was the cause of death in 3 cases. Infection of the abdominal wall developed in 2 cases following resection and in the third peritonitis developed 2 days following repair of a jejunoileal fistula that was caused by the crushing of the spur of a colostomy that had been performed elsewhere. The fourth patient of the 6 died of gangrenous cholecystitis following closure of a colonic stoma. The fifth patient a woman, 71 years old, whose intestine was acutely obstructed died from bronchopneumonia 21 hours after colostomy. The sixth patient died of cerebral hemorrhage 14 days following an exteriorization operation and abdominal hysterectomy.

COMMENT

We are convinced that the improved results obtained in series B are definitely attributable to chemotherapy. Nevertheless, the two series of cases are not altogether comparable because, in the past 20 years, other changes in routine surgical management in all colorectal cases may have influenced the results. A more

Fig. 1 Mortality among patients subjected to operation for malignant lesions of the large intestine and rectum, 1934-1945

accurate appraisal of the value of chemotherapy in surgery of the colon could be obtained by comparing the results of two large series of colonic cases in which conditions were practically identical except that chemotherapy was employed in one series.

Since the organization of a special colon service in the Mayo Clinic nearly 20 years ago all patients with lesions of the colon and rectum who are considered candidates for major surgical treatment have received pre-operative treatment in the hospital for 3 to 5 days or longer depending on the condition of the patient. The principal objectives of the treatment are (1) to decompress and cleanse the large bowel (2) to combat loss of blood and to establish and maintain protein balance by blood transfusions (3) to combat dehydration by intravenous injection of saline and glucose solutions (4) to establish and maintain concentration of vitamins especially as regards vitamins C and K (5) to combat potential infections by chemotherapy.

In the fall of 1939 we began using the sulfonamide compounds in colonic surgery. At first perhaps because of the surgeon's innate skepticism concerning the value of drugs especially any drug with such advance build up as had been given to the sulfonamide compounds 5 to 10 grams of the crystals were only occasionally placed in the peritoneal cavity prior to closure of the wound in those cases in which peritonitis was feared because of actual or suspected soiling. As experience enlarged the surgeon slowly and perhaps with reluctance became convinced of the effi-

cacy of the sulfonamide compounds and began to use them routinely. Since 1942 following the research of Poth succinyl sulfathiazole (sulfasuxidine) has been given by mouth routinely as a preparatory measure 12 to 15 grams daily over a period of 3 to 5 days. In recent years after the supply of penicillin became readily available, this substance has been used frequently as an added measure of therapy. Other than the introduction of chemotherapy there has been in the Mayo Clinic no major change in the management of colonic and rectal lesions during the past 12 years. Since therefore there was only one variable factor of importance in the management of patients during this period, it appeared worth while to compare the immediate surgical results in cases in which the patients had not had the benefit of chemotherapy with those in which the patients had received it. For this purpose the yearly hospital mortality rate of all patients who had undergone any operation for carcinoma of the colon or rectum from 1934 to 1945 inclusive was computed. As Figure 1 reveals, the mortality rate before 1939 varied between 15 and 20 per cent. A slight drop occurred in 1939 the year in which the sulfonamide compounds were first casually or intermittently used and then in 1940 there was a precipitous drop to around 5 per cent where the rate has since remained.

In addition the yearly surgical and resectability rates for the same 12 years were determined. The surgical rate is defined as the number of cases in which operation was performed divided by the total number of cases

Fig. 2. Resectability rate of patients with malignant lesions of large intestine and rectum, 1934-1945.

in which a diagnosis of carcinoma of the colon or rectum was made. The resectability rate is the number of patients on whom resection was performed divided by the number of patients on whom operation was performed. As indicated in Figure 2 there has not been a decline either in the surgical rate or in the rate of resectability during the years of decline in mortality. Instead, there has been an appreciable rise.

Finally in order to determine the influence of the factor of infection on the hospital mortality rate the cause of death of all patients in this series was tabulated. Since peritonitis and pneumonia are unequivocally infections, it seemed pertinent to compare the incidence of these two complications as a cause of death in those cases in which the patient had received little or no sulfonamide compound with those in which the patient had received adequate dosage of sulfonamide. As indicated in Figure 3 the mortality rate in each category decreased as the years passed.

The changes that have occurred in surgery of the colon since the introduction of chemotherapy have been as spectacular and revolutionary as the changes wrought by iodine therapy in surgery of exophthalmic goiter. The analogy is striking. In the preiodine era of thyroid surgery for exophthalmic goiter technical perfection of the surgical procedure of partial thyroidectomy was no definite assurance that the patient would endure the

operation for not infrequently severe hyperthyroid crisis would supervene, resulting in fatal issue. Likewise, in the era of colonic surgery before chemotherapy was available, technically errorless resection of a segment of bowel was not definite assurance that the patient would survive, for not infrequently infection would spread to produce fatal peritonitis. The surgeon who worked in each field after resorting to refinements of technique and other measures, finally learned that the best means of combating the hidden danger (acute hyperthyroidism in the one and spread of infection in the other) was to divide the operation into stages. In both fields, employment of stage procedures resulted in marked improvement but only partially eliminated the hidden dangers peculiar to each. Thus it was only after preoperative iodine therapy had been standardized that the surgeon could be reasonably assured that, barring some accident, his patient with exophthalmic goiter would endure an uncomplicated partial thyroidectomy in one stage. And so, in the field of colonic surgery only in recent years, since the advent of chemotherapy could the surgeon be reasonably confident that his patient with a lesion of the colon or rectum would survive an uncomplicated resection of the colon. Finally as the statistical data obtained in the preiodine era were not a sound basis for appraisal of modern thyroid surgery so the results in the era before chemotherapy

Fig. 3 Causes of death. Mortality from various causes of death following operations for malignant lesions of the colon and rectum, 1934-1945.

are not a fair basis for judging modern colonic surgery. Although iodine and chemotherapy each has markedly reduced the incidence of the most dangerous complication in its respective field, it must be strongly emphasized that both forms of therapy must be considered as extremely valuable adjuncts to surgery put by no means as substitutes for the proved principles of sound surgery.

The marked reduction in the hospital mortality rate associated with the surgical treatment of diverticulitis suggests that the indications for surgical treatment should probably be broadened. As indicated previously there is general agreement that uncomplicated diverticulitis should be managed conservatively and that surgical treatment should be advised only if complications have developed. Non-surgical treatment has definite limitations. It cannot be relied on to bring about complete subsidence of the inflammatory process nor to prevent development of complications which will require operation nor even to free the patient from his symptoms. It follows that in many cases under nonsurgical management the patient has some disability and there is always the possibility of the subsequent development of complications which will require operation. Furthermore, as we have demonstrated, the safest type of opera-

tive treatment for complicated diverticulitis is the establishment of a colonic stoma orad to the inflammatory segment of bowel followed by resection of the involved segment after many months of the patient's living with his colonic stoma. Both the reluctance to advise surgical treatment and the choice of staged operations in the past are readily understandable in view of the former mortality rate of approximately 15 per cent. With a reduction of the mortality rate to about 4 per cent the proposal that operations should be advised for less complicated diverticulitis may be seriously entertained. It is probable, as well, that the surgical mortality rate could be reduced even further if patients with less extensive disease were operated on and certainly a greater number of single stage procedures and even resections with primary anastomoses could be carried out safely. The advantage of removal of the involved segment of bowel with subsequent cure of the patient, is evident when the uncertainty associated with nonsurgical management is considered.

SUMMARY

While the great majority of patients suffering from diverticulitis of the sigmoid portion of the colon respond satisfactorily to nonsurgical management, the complications of per-

foration obstruction and fistula usually require operation. Surgical exploration and frequently resection of the involved segment of colon are indicated at times because of the impossibility of distinguishing with certainty between carcinoma and diverticulitis. In the present series carcinoma could not be excluded with certainty in about 25 per cent of the cases in which a preoperative diagnosis was ventured.

Local excision of an inflamed diverticulum or local excision of a fistula and closure of the wall of the bowel was possible rarely but was followed by unsatisfactory results in approximately half of the cases in which it was attempted.

The establishment of a colonic stoma oral to the lesion was associated with a hospital mortality rate of 5.1 per cent in those cases in which treatment was given in the era before chemotherapy was available and with a rate of 1.1 per cent in those cases in which chemotherapy was employed. Excluding a small group of patients who died essentially of pelvic abscess and infection a large percentage of the patients with a colonic stoma oral to the lesion remained clinically well as long as the stoma was maintained. Of the patients whose stomas were closed and resection of the bowel was not done, only about a third remained well. Results following closure of the stoma without previous resection of the involved segment of bowel were so unsatisfactory that we are of the opinion that as a rule, resection should be done in all cases unless proof can be established of complete subsidence of the inflammatory process.

The safest plan of treatment proved to be establishment of a colonic stoma oral to the lesion followed after an interval of 6 to 12 months by an exteriorization type of resection. Resections of this type were associated with a hospital mortality rate of 13.6 per cent in the era before chemotherapy but there were no deaths after chemotherapy became available. The results after both primary resection and following resections done after establishment of a colonic stoma were satisfactory in that approximately 80 per cent of the patients were cured. The results were less

satisfactory in the group of patients who underwent primary resection with end-to-end anastomosis of the bowel.

The employment of modern chemotherapy in the surgical management of complicated diverticulitis of the sigmoid has partially eliminated the occurrence of serious infections and thereby has been the major factor in the marked reduction of the surgical mortality from 14.7 per cent to 4.2 per cent.

With the risk of operation so markedly reduced and in view of the obvious advantage of resection serious consideration can be given to broadening the indications for surgical treatment for diverticulitis.

METHODS FOR DIFFERENTIAL DIAGNOSIS OF PAINLESS JAUNDICE

JOHN R. ROBINSON M.D., Kankakee, Illinois, and CARL A. MOYER, M.D. Dallas, Texas

MUCH has appeared in the recent literature concerning the differential diagnosis of surgical jaundice (1 3 5 7 8 11). We are presenting here a few simple, practical methods for this differential diagnosis based on clinical and laboratory data of a type practicable even by those with limited laboratory facilities. Many of the recent articles stress the use of complex laboratory examinations which require highly skilled and specially trained technicians. The tests herein included can be performed in any ordinary laboratory and have been exact enough to enable accurate diagnosis 98 per cent of the time.

Painful jaundice is almost always due to stones and therefore presents little in the way of a diagnostic problem though occasionally hepatitis may cause confusion. Painless jaundice, however, presents a somewhat complex diagnostic problem due to the great group of hepatitides. This diagnostic problem is simplified if one is familiar with the normal physiology of bile pigments and with the basic abnormal physiology of the various types of jaundice, and in addition makes use of the common basic laboratory tests required for the differential diagnosis of painless jaundice.

In Figure 1 is seen the normal physiology of bile pigments (2). Bilirubin I designates that form of bilirubin which has not entered the liver cell and bilirubin II represents that form of bilirubin which is either in or which has passed through the liver cell. Also from the diagram one sees how urobilinogen is formed by a process of reduction of bilirubin II in the intestine. Urobilinogen is then excreted in part in the feces and reabsorbed in the portal blood. Normally the reabsorbed pigment is practically all re-excreted in the bile. The junction of the arrow to the

kidney with the arrow of reabsorption indicates the passage of urobilinogen into the blood and its excretion by the kidney when urobilinogen is presented to the liver faster than the liver is able to reconvert it to bilirubin II.

The physicochemical properties of bilirubin I and bilirubin II are of importance as a basis for the understanding of certain laboratory data. Bilirubin I is a colloidal compound which is readily oxidized and passes slowly into the tissues with the result that high concentrations are necessary before clinical jaundice is manifest. Bilirubin I is insoluble in water and Ehrlich's solution but is soluble in alcohol. Bilirubin II is also a colloidal compound but is combined with bile salts. It is slowly oxidized and passes readily into the tissues and is therefore visible at lower levels than is bilirubin I. Bilirubin II is soluble in water, Ehrlich's solution and in alcohol.

The common basic laboratory tests required for the differential diagnosis of jaundice are (1) Van den Bergh reaction (2) Pettenkofer test, (3) Hay's test (4) Gmelin's test (5) foam test, (6) galactose tolerance test. All of these tests are required and should be used in conjunction with other clinical data.

The Van den Bergh reaction a modification of Ehrlich's diazoreaction is employed for the detection of bile pigments in the blood serum. There are two main types of the reaction based upon whether the bile pigment has or has not passed through the liver cell. The direct reaction occurs with bilirubin II and is chemically possible because of the solubility of the substance. One cubic centimeter of Ehrlich's solution is added to 1 cubic centimeter of serum and within 30 seconds a violet color of bilirubin is formed. The indirect reaction occurs with bilirubin I and is also based upon its solubility. One cubic centimeter of serum plus 2 cubic centimeters of 95 per cent alcohol plus Ehrlich's solution results in a reddish

From the Kankakee Clinic, Kankakee, Illinois, and the Southwestern University Medical School, Department of Surgery, Dallas, Texas. Both authors formerly from the Department of Surgery, Wayne County General Hospital, El Paso, Michigan.

Fig. Bile pigments.

violet color developing immediately. The direct reaction is usually indicative of obstructive jaundice or some condition in which bilirubin II is present in the blood stream. There are two subreactions under the direct type namely the delayed direct and the biphasic reaction which usually indicate a jaundice due to liver damage. The indirect reaction due to bilirubin I is commonly seen in hemolytic jaundice and collections of old blood. Normal serum will also give the indirect reaction. All sera which give the direct test will also give the indirect test. The indirect test is used as a quantitative measure of serum bilirubin. When the bile salt concentration in the blood is elevated a direct test results because bilirubin II is formed when bile salts are added to normal serum.

The Pettenkofer test for bile salts is performed by adding 10 per cent cane sugar solution plus 3 drops of concentrated sulfuric acid to 5 cubic centimeters of the fluid to be tested. If bile salts are present a red ring will form at the junction of the solutions. The red colored ring is due to cholic acid.

The Hay's test depends upon the phenomena of lowered surface tension which is produced by the bile salts. This action is due to the fact that bile salts act as wetting agents. Flowers of sulfur are added to the solution to be tested and sink immediately when the urine contains over 0.5 milligram per cent of bile salts. They sink with agitation in the range between 0.0025 and 0.5 milligram per cent. In solution containing less than 0.0025 milligram per cent the flowers of sulfur will float in spite of agitation. This test is the basis of

a quantitative determination of bile salts in the urine (13).

The Gmelin's test is used to detect bile in urine. The fluid to be tested is passed through a moistened filter paper to which is added a drop of fuming nitric acid which oxidizes pigments resulting in a series of colored compounds yellow red green violet.

The foam test is the most simply conducted for the detection of bile in the urine. It consists of a greenish foam forming over the solution when it is shaken. This action is also based on a lowered surface tension.

The Icteric Index is of no additional value when the quantitative Van den Bergh reaction is used and therefore merits no discussion.

Another test of considerable value is the galactose tolerance test which is based upon the principle that galactose is not converted to glucose by the liver when considerable damage is present. Because this is only a rough test of liver function and considerable liver damage must be present before the test is impaired, it lends itself admirably to the purpose. This test consists of giving 40 grams of galactose and checking the urinary excretion. In the normal patient less than 3 grams will be excreted in the urine in a 5 hour period. In jaundice due to or with severe liver damage the amount of excretion will vary from 4 to 6 grams in 5 hours depending upon the degree of liver impairment.

The final important laboratory test is the Schmidt's test for the detection of urobilin concentration in the stools. The stool is incubated for 24 hours with Ehrlich's reagent and a quantitative estimation is then made of the diazobilirubin resulting. If the concentration is below 5 to 10 milligrams, the test is said to be negative. If it is above, it is positive. The presence of urobilin in the stool of course indicates that bile is getting into the intestinal tract to form urobilinogen (9, 13, 15). Urobilinogen in urine may be detected by a similar method but without incubation. Watson has recently described a semiquantitative method for urobilinogen in stool and urine which may be used (9, 15).

The basic examinations for diagnosis in a given case are therefore first conducted on the urine to determine the presence or absence of

bile and urobilinogen on the stool to determine the quantitative amount of urobilin on the blood to determine the size shape number and character of the red blood cells the quantitative amount of bilirubin in the serum, and the type of Van den Bergh reaction obtained. The galactose liver function test is then carried out to determine the degree of impairment present.

In the nonobstructive type of jaundice, the abnormal physiology is briefly that bilirubin I is formed more rapidly than the liver can convert it into bilirubin II. This occurs in three abnormal physiologic states

The first of these states is the condition in which the liver is normal but the blood cell destruction is markedly increased. The clinical examples of this group are the so-called acholuric jaundice congenital hemolytic icterus and toxic hemolytic icterus. The results of the basic examinations for this type of physiologic disturbance are based upon a high bilirubin I content in the blood. The Van den Bergh reaction is indirect and of variable quantity usually rather high. The urine contains no bile nor bile salts but has an increased urobilinogen content the stool will show a positive Schmidt's test and the galactose tolerance will be less than 3 grams in 5 hours indicating normal function of the liver.

The second state is that in which the liver is moderately impaired and the blood cell destruction moderately increased. The clinical representatives of this group are black water fever and pernicious anemia. Examination of the urine and stool show findings similar to the first state also the Van den Bergh reaction both quantitative and qualitative, will be similar. The diagnostic differences will be found in examination of the red blood cells and by an impaired galactose tolerance, approximately 4 grams excretion in 5 hours.

The third state in which this occurs is that seen when the liver is severely impaired and the red blood cell destruction remains normal. This is clinically seen theoretically in severe terminal cirrhosis. The diagnostic laboratory finding is a markedly impaired galactose tolerance test usually around 6 grams excreted in 5 hours. The values for the quantitative

Van den Bergh will usually be considerably lower than in the other two states but may terminally closely approximate them.

Several other points in the differential diagnosis of nonobstructive jaundice are of the utmost importance (1 5 7) In hemolytic icterus the signs of increased bone marrow activity are present there is an anemia if the breakdown of red blood cells is more rapid than the bone marrow can supply cells with a normal hemoglobin content. In the congenital form of hemolytic icterus the red cells are spherocytic, are more fragile than normal and the serum contains an elevated specific hemolysin titer. In the toxic hemolytic icterus the specific hemolysin titer and the cell fragility are normal. The diagnosis of jaundice occurring in pernicious anemia and thrombopenic puerpera is corroborated by the other clinical signs by the symptoms and by the laboratory findings of the diseases.

Obstructive jaundice is divided into two classes based on the site of the obstruction namely intrahepatic and extrahepatic.

Intrahepatic obstructive jaundice results from a diffuse hepatitis (4 10 14) which causes edematous occlusion of the small bile canaliculi of the liver. The effect of such occlusion is partially to obstruct the ducts in the same manner as the stone in the extrahepatic system. Bile pigments pile up behind the obstruction and result in an increase of the obstruction. Intrahepatic obstructive jaundice is always incomplete. The etiology of such jaundice may be divided into six groups (1) Viral—catarrhal jaundice usually follows an upper respiratory infection in a young adult and is of approximately 30 days duration. It is characterized by progressive jaundice for about 21 days followed by rapid regression in about 10 days. (2) Drugs—the widespread use of sulfonamides both externally and intraperitoneally is responsible for this type. It is usually seen with massive overdose of the drug such as results from intraperitoneal implantation in the presence of a partially impaired liver. The halogen derivatives may also be responsible for this type of jaundice, anesthetic agents and hypnotics being the most frequent causative agents. (3) Bacterial—this is most commonly the re-

Fig. 1. Diagram showing normal bile salt distribution.

Fig. 2. Diagram showing normal bile salt distribution.

sult of a diffuse ascending cholangitis (4) Spirochetel-Weil a disease with its two causative organisms icterohemorrhagica and canicola, is the example of this. (5) Neoplasms—diffuse primary neoplasms of the liver are rare and therefore an unlikely cause but metastatic neoplasms or diffuse leucemic infiltrations may result in such a picture. (6) Hepatic congestive heart failure if severe and longstanding may produce this type of jaundice.

The Van den Bergh reaction in intrahepatic obstructive jaundice is indirect early due to an increase of bilirubin I pigments but it later changes to a delayed direct or biphasic reaction. The urine has bile, and bile salts may be increased. The urobilinogen content is increased (12) or normal. Schmidt's test on the stool vary from day to day due to the variation in the degree of obstruction of the bile canaliculi. The average case will show a sequence as follows: 3 or 4 positive reactions, 1 negative reaction, 2 more positive reactions, another negative reaction. There is an impairment in galactose tolerance with a resultant excretion of 4 to 5 grams in 5 hour period.

Extrahepatic obstructive jaundice may be due to stones, strictures, or neoplasms located in the hepatic ducts, the common hepatic ducts, the common duct or the ampulla. If complete obstruction is present in extrahepatic jaundice, there is a 95 per cent chance that the cause is a neoplasm either in the common duct, ampulla or head of the pancreas. Such a case has only a 5 per cent chance of

being a stone. In a case with incomplete obstruction the chances are that 95 per cent of the time a stone is the etiological agent in 5 per cent of such cases, a neoplastic obstruction may be the cause (15). Neoplastic obstruction of this type is usually due to direct extension from a carcinoma of the stomach or colon. The primary question in diagnosing this type of jaundice is—"Is the obstruction complete or incomplete?" To determine this point we must again fall back on our laboratory studies. The Van den Bergh reaction in both cases will be immediate direct but the amount of bilirubin in the incomplete obstruction is usually below 10 milligrams per cent whereas in the complete, it is generally above 10 milligrams per cent. In the complete, the Schmidt's tests on the stools will be consistently negative in the incomplete, they will vary from positive to negative depending upon the position of the obstruction. Examination of the urine in both cases will reveal bile but there will be absolutely no urobilinogen in the urine in the complete obstruction. The urobilinogen will vary from day to day in the incomplete types.

Figures 2, 3, 4, 5 represent in diagrammatic form the normal and altered physiology of the bile pigments and the bile salts in complete and incomplete obstruction. The diagrams are self-explanatory; the arrows representing the course of the pigments and bile salts under normal and abnormal conditions. It can be seen in the diagrams that the conjugation of the bile salts in the liver cell is dependent upon the available glycine.

Fig. 4. Normal circulation bile pigment.

In conclusion the pertinent data from 5 recent ward cases are presented together with the completed scheme of differential diagnosis in each case. In each of these cases the diagnosis was verified by operation or postmortem examination.

CASE 1. Painless jaundice of 2 weeks duration liver palpable and smooth soft palpable spleen urine negative for bile positive for urobilinogen 1/120 Schmidt's positive 4 times, Van den Bergh delayed direct, serum bilirubin 2.8 milligrams per cent, hemoglobin 8 grams, red blood cells 3.00 with many small irregularly formed cells, fragility test normal normal hemolysis titer galactose tolerance test 3 grams in 5 hours.

The primary diagnosis in this case is nonobstructive jaundice. Next, the physiologic group in nonobstructive jaundice which best fits this case must be determined. Since the galactose test is normal it can be assumed that the liver is functioning satisfactorily. This case therefore falls into the group with a normal liver but increased red blood cell destruction rate. The causes of this type of jaundice are (1) hemolytic icterus which may be divided into two types: congenital—with the high titer of specific hemolysin and the fragile red cell toxic with the normal red cell and hemolysin titer (2) hemosiderosis may be diagnosed by taking a skin biopsy and staining for the Prussian blue reaction, (3) pernicious anemia may be diagnosed by the blood picture, bone marrow smears, and response to treatment. The most likely diagnosis in this case is, therefore, toxic hemolytic icterus.

CASE 2. Painless jaundice of 5 days duration, liver large, soft and tender spleen not palpable, heart and lungs normal urine positive for bile and urobilinogen in dilutions of 1/60 Schmidt's positive 5 times direct Van den Bergh, serum bilirubin 8 milligrams per cent, red blood cells 3.75 hemoglobin 60 per cent galactose tolerance 5 grams in 5 hours.

The primary diagnosis of this case is obstructive jaundice. The physiologic group is determined by

Fig. 5. Bile pigment circulation complete obstruction (neoplasm).

the presence of bile in the stool and is obviously the incomplete. Next we must determine whether this incomplete jaundice is extrahepatic or intrahepatic in origin. Since the galactose test shows impairment indicative of liver damage, we can assume that the jaundice is of intrahepatic origin. The most likely diagnosis is, therefore, incomplete intrahepatic obstructive jaundice that is hepatitis.

CASE 3. Painless jaundice of a weeks duration moderate dyspepsia small palpable mass in midline above the umbilicus, urine positive for bile and urobilinogen 1/40 dilution Schmidt's 1 minus and 3 pluses 4 plus occult blood in stools, Van den Bergh direct, serum bilirubin 8 milligrams per cent, red blood cells 3.75 hemoglobin 60 per cent, galactose tolerance test 3 grams in 5 hours, x ray films showed absent peristalsis in pyloric region of stomach.

The primary diagnosis of Case 3 is obstructive jaundice. The physiologic group determined by the presence of bile in the stool is the incomplete. Since the galactose test is normal we assume this jaundice to be of extrahepatic origin. Because it is extrahepatic, there is 95 per cent chance of it being a stone and 5 per cent chance of it being a neoplasm involving the duct system in some way. In view of the occult blood, the palpable mass and the persistent pyloric x ray defect, the diagnosis of an extrahepatic incomplete obstructive jaundice due to carcinoma of the stomach with secondary involvement and obstruction of the right hepatic duct was made and verified by autopsy.

CASE 4. Painless jaundice for 5 days duration hematemesia 2 times, liver and spleen not palpable, urine negative for bile, contained urobilinogen 1/160 dilution Schmidt's test positive 3 times, Van den Bergh direct, serum bilirubin 5 milligrams per cent, red blood cells 4.60 hemoglobin 40 per cent, galactose tolerance test 5 grams in 5 hours, normal fragility test and platelet count.

The primary diagnosis of Case 4 is nonobstructive jaundice. The physiologic group as determined by an impaired galactose test and a normal fragility test is that group with the impaired liver and normal red blood destruction rate. The cause of this type of

jaundice is usually a severe terminal portal cirrhosis. The diagnosis in this case was, therefore, terminal portal cirrhosis in atrophic phase with esophageal varices. The direct Van den Bergh reaction resulted in this case from an increased concentration of bile salts in the blood stream due to failure of the impaired liver to handle the bile salt circulation properly.

CASE 5. Painless jaundice of 3 weeks duration liver and spleen not palpable urine positive for bile 4 times negative for urobilinogen stool negative for bile 6 times Van den Bergh direct serum bilirubin 17 milligrams per cent urine grossly bloody on one occasion cystoscopic and pyelogram examination negative except for trigonitis, galactose tolerance test 3 grams in 5 hours.

The primary diagnosis in this case is obstructive jaundice. The physiologic group as determined by the presence of bile in the urine and the absence of bile in the stool is therefore the "complete." The galactose tolerance test is normal therefore this is a case of extrahepatic complete obstructive jaundice and has a 95 per cent chance of being a neoplasm involving the duct system and a 5 per cent chance of being a stone. The urinary bleeding ceased upon the administration of vitamin K. Subsequent operation and biopsy proved the lesion to be carcinoma of the lower third of the common bile duct.

SUMMARY

A simplified method for diagnosis of jaundice based on common easily performed

laboratory examinations is presented together with several cases to illustrate how the method may be applied to a given case.

RADIATION INJURIES

INJURIES incurred by physicians working with the roentgen rays or radium in the early days were so much publicized that nearly every case was known and discussed. Nowadays with the greatly augmented number of physicians and assistants administering x ray therapy and participating in x ray diagnostic work the much larger percentage of injuries sustained remain almost unheralded. The importance of recognizing and avoiding these dangers from irradiation is not given sufficient emphasis. Surgeons can testify to the increasing number of physicians and dentists for whom they are called upon to repair irradiation damage to hands, and yet these injuries include only a part of the extensive category of damages which radium and x rays may cause.

The surgeon who employs the fluoroscope as an aid in the removal of foreign bodies or in the adjustment of malapposed fractured bones, unless especially trained in radiology

subjects himself and his colleagues as well as the patient to danger of dermal injury to say nothing of systemic damage to the blood making organs and especially of damage to the leucocytes. We find physicians even specialists in radiology who have suffered as a result of self administered irradiation. The writer recalls very well a surgeon who treated his own hand with radium with resulting irreparable radium injury malignant degeneration and finally miserable death from pulmonary metastases. Another well known radiologist of vast experience permitted himself to continue to assist in the adjustment of fractured bones and in the removal of foreign bodies under x ray control until his own hands developed advanced skin damage, with subsequent malignant degeneration and fatal pulmonary metastases. The young physician just graduated from medical school and internship who succumbs to the importunities of the salesman of x ray equipment and buys his own fluoroscope for use in his office may yield to the temptation to use the x rays in fluoroscopic management of fractures or foreign bodies. Unless he takes proper precautions he is likely within a couple of years, to suffer such damage to his hands that he will need extensive plastic surgery with replacement of skin of the injured members. Even veterans in radiology who have always used leaded gloves and palpating spoons often find themselves with degenerating skin damage requiring plastic surgery in order to save their lives, to say nothing of relieving the constant pain caused by the chronic x ray injuries.

It is possible to make reasonably safe use of the x rays for all of these purposes. For the removal of foreign bodies under the fluoro-

scope an accumulated time of 10 minutes at 3 milliamperes will emit the maximum radiation which should be utilized in any given case and no one, surgeon or radiologist should participate in such operations any oftener than occasionally certainly not routinely.

There are numerous ways of accomplishing satisfactory removal of foreign bodies by other than fluoroscopic means in fact, it is now often possible to substitute for potentially dangerous x ray methods the use of electronic or telephonic foreign body finders. Radiologists should be among the first to urge the adoption of these non radiological methods because they offer a means of by passing the danger inherent in the x ray method.

Every piece of diagnostic equipment used for fluoroscopy should have a built in protecting filter of 10 millimeter of aluminum or its equivalent and under no circumstances should this be removed. The size of the field of illumination on the screen should be reduced to the very minimum. Long handled forceps should be employed. The image of the bones of the hands of the operator or radiologist should never be seen on the fluoroscopic screen. The roentgen tube should never be activated even for a second unless the observer's eyes are focused upon the screen ready for instant observation and in no case should the apparatus be excited until after the observer's eyes have been thoroughly adapted to the dark.

The insidious character of the dangers resulting from small repeated exposures to x ray and radium is one important explanation of failure to take protective precautions. The direct injury to the cellular structure of the surface of the hands is usually not evident until months or even years after exposure.

It has been said that the three most important protective devices for the operation of x ray equipment and for the use of radium are

training, common sense and experience, and the most frequent causes of injury are carelessness and ignorance. We are told that between 1919 and 1935 there were seen at the Mayo Clinic 135 physicians with x-ray injuries, of whom 91 contracted their injuries during fluoroscopic fracture reduction. Of these 78 admitted failure to take protective precautions, and 11 confessed that they kept the use of protective gloves only after sustaining the injury.

The foregoing remarks relate principally to damage to the hands, but other systemic dangers threaten the radiologist. These dangers are all the more threatening to the physician who owns x ray equipment and without adequate training undertakes to use it occasionally especially for fluoroscopic work. No one can suppose for a moment that fluoroscopy gives adequate information except in a rather limited field as, for instance, in the examination of the chest.

The fluoroscope shows the excursion and the relative height of the phrenic cupolas, the condition of the phrenic angles, the mobility of the heart in relation to the diaphragm, the esophagus, and gross lesions of the chest. It is impossible for even the most expert and the most experienced to see as much tissue detail in the fluoroscope as can be seen on the films. The fluoroscope can never take the place of the films. It does, however, supplement the film study in an indispensable manner. Fluoroscopy gives information as regards the size of the heart and the movements of the walls of the different chambers of the heart. The pulsations of the aorta and of vascular tumors can be studied and differential diagnosis made in some cases although the absence of pulsations does not mean that a certain shadow is not due to a vascular tumor and the presence of a pulsation does not mean that the tumor is of the aorta. Transmitted pulsations are dif-

EDITORIAL

difficult to differentiate from intrinsic pulsations.

It might be assumed that radiologists are so conscious of the hazards of their specialty that they do not need to be reminded of these dangers but a survey of forty five hospitals¹ showed that both radiologists and technicians receive considerably more radiation during fluoroscopy than they were aware of. These exposures were the most excessive noted in the survey. Cutaneous effects varying from

atrophy of the skin to the formation of epithelioma were noted in 20 per cent of the radiologists seen in the hospitals of this survey.

The remedy for this deplorable frequency of x ray damage lies in education. The radiologist should know better. Others such as general surgeons and especially gynecologists, urologists, and dermatologists as well as dentists should make a special study of radiation physics before attempting to employ x ray apparatus or radioactive substances.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

AN excellent and concise review of the author's long experience following scrotal circulation studies and surgical treatment of varicoceles with symptoms is presented in *Varicocele semiologia* by Bernardi. The author credits Ivanissevich with correcting misconceptions and teachings of previous writers in regard to the venous circulation of the male genital organs. By the use of phlebography the author was able to show for the first time the anastomosis of the anterior and posterior venous systems in cases of large varicoceles. The anatomy of the return venous circulation and the preoperative and postoperative results are very well illustrated in this volume.

Under semiology of varicocele the author discusses scrotal elongation, scrotal measurement, recognition of the posterior venous ectasia, palpatory maneuver for the anteroposterior venous communication, recognition of the spermatic artery and palpatory classification of varicoceles.

The author carefully reviews the anatomy of the inguinal canal and finds its average length only 3 to 5 centimeters rather than 4 to 5 centimeters and the internal orifice of the canal is usually found 1 centimeter above the crural arch. A 3 to 4 centimeter skin incision beginning a fingerwidth above the external inguinal ring is described. The external oblique is incised and by palpation the internal ring may be recognized beneath the aponeurosis. The technique of opening the tunica fibrosa, identification and division of the internal spermatic vein and all its associated trunks are well described in detail. Venous trunks, no matter how small should not be over looked at the time of operation. Abdominal pressure may distend and help visualize the smallest veins by reflux.

The author states that ligation of the spermatic trunks at the internal orifice of the inguinal canal constitutes a direct and causal treatment of varicocele. Section and ligation produce a slow and progressive reduction of the dilated vessels with absolute disappearance of the reflux. If reflux persists the patient is not cured in the strict medical sense even though the symptoms have been improved. Bernardi sincerely believes that no other procedure is capable of providing at one and the same time so high a percentage of cures and greater simplicity and security in its execution with such absolute respect for the spermatic artery and the gland as the one mentioned in this compendium.

This volume is an excellent reference covering of the newer concepts of simple varicoceles. The surgical technique for division of the inguinal spermatic vein is well illustrated and described.

LEONARD W. EN

THE well known treatise on endocrinology first appeared in 1941. *Essentials of Endocrinology* by Grollman has been revised and largely brought up to date. The current edition is characterized by the same excellent features that were widely recognized when the book first appeared. It is such up of a systematic discussion of each of the recognized endocrine glands in their anatomical, physiological, chemical, pathological, and clinical aspects. The author has been primarily concerned, it would appear, to produce a book that would be useful to clinicians though it is also valuable for laboratory investigators. It is probable that only the latter will have such occasion to take issue with the author and the discrepancies will be few and mostly of no great moment.

Less than justice has been done to recent brilliant studies of the thyrotropic hormone and its influence on the intimate enzymatic processes in the thyroid gland as brought out by such students as Despey-Salter and Chalkoff. The newer work utilizing radioactive iodine as a tracer substance is also inadequately considered. The older work of Cannon on the emergency function of the adrenal medulla is again mixed with a perfunctory nod. The cortex of the adrenal fares little better. Grollman still persists in the now rather unique opinion that this structure forms but a single hormone despite the fact, which he cites, that at least three categories of effects of cortical deficiency are clearly evident and that active fractions of cortical extract are known selectively to influence these processes. The important adaptive function of the adrenal cortex in relation to stress is inadequately treated as is that structure as an accessory sex organ. Throughout the book an occasional impatient phrase is substituted for adequate judicial consideration of the pineal gland is a case in point. The discussion of the pineal gland is a case in point. Another feature that is annoying at least to those readers who are interested in the "who's who" aspect of the subject, is the common relegation of a few of the authorities cited to the bibliography.

One of the unique features of the book is an especially good interpolated chapter on the hypothalamus.

ESSENTIALS OF ENDOCRINOLOGY. By Arthur Grollman, Ph.D. M.P. F.A.C.P. and ed. Philadelphia, London, Montreal J. B. Lippincott Co. 647

REVIEWS OF NEW BOOKS

in relation to clinical disorders that suggest, but have not been shown to be endocrinopathies. The possibility was overlooked however that these disorders may be due to hypothalamic influences transmitted humorally to the anterior pituitary, as Long has suggested in relation to thyrotropin discharge.

The illustrations are nearly all well selected and a considerable proportion of them are original. The proofreading has been ably competent. So logically has it been organized, and so adequate are the headings, that the vast wealth of incorporated material is easily accessible. Altogether the book is recommended as one of the best in this difficult field.

ROY G. HOSKIN.

In a book of 416 pages entitled *Synopsis of Operative Surgery* the author H. E. Mobley presents surgical procedures covering all systems and regions of the body. There are many illustrations, most of which are of the schematic form used in older texts. The descriptions are oversimplified and lacking in detail necessary for students or less experienced surgeons. There is, however, much useful information and many worth while helpful suggestions.

ROSELL T. BOWNE.

THE well prepared monograph *Penicillin Therapy* by John A. Kolmer is a very timely contribution for the practicing physician as well as the medical and surgical specialist in an era characterized by such rapid advances in the field of chemotherapy. The author has reviewed the voluminous literature on this subject and has concisely summarized the most important contributions which have been made. The book is largely written from a clinical standpoint and the major portion of it is concerned with the clinical phases of practical penicillin therapy including available methods and routes of administration. Other chapters deal with the history, production, methods of assay and properties of penicillin and streptomycin.

Detailed descriptions of the methods for measuring the concentration of chemotherapeutic agents in the various body fluids and for determining bacterial susceptibility should be very valuable to the medical technician. The established principles of therapy with penicillin, streptomycin, and other antibiotics are discussed. In summarizing the experiences of others the author often quotes conflicting viewpoints which may tend to confuse the reader somewhat, although a detailed and acceptable plan of treatment is always given for each disease. The book is well arranged adequately illustrated and well edited. Each chapter is followed by a complete annotated bibliography. It should be valuable not only as a reference book, but also as a practical guide to effective chemotherapy.

W. A. ALSTERMEYER.

SYNOPSIS OF OPERATIVE SURGERY By H. E. Mobley M.D. F.A.C.S. 1st ed. St. Louis: The C. V. Mosby Co. 647 pp. 1947.
PENICILLIN THERAPY By John A. Kolmer M.D., M.D. Dr. F.H. Scott M.D. L.H.D. F.A.C.P. and ed. New York, London: Appleton-Century Co. 1947.

THE author of *Dr. Samuel Guthrie Discoverer of Chloroform* had prepared a short paper about the almost forgotten discoverer of chloroform and thought it worthwhile to bring together what little was known about this man and his work. The result is a small volume depicting Dr. Samuel Guthrie as a pioneer physician and a scientific investigator of unusual intelligence and of varied interests.

Footnotes and collateral notes, placed at the end add items of interest to the story. In the appendix are reproduced a few family papers and several papers from the *American Journal of Science and Arts* 1831-1833 which contains all of the contributions of Dr. Guthrie. Numerous illustrations are included in this attractive book which will be enjoyed by those interested in the history of anesthesia, the development of firearms and in the life in remote settlements of a century ago.

MARY FRANCES POT.

FOR the past few years it has been increasingly difficult for the practicing physician as well as all other scientists who are not working in the field of blood grouping and blood antibodies to keep abreast of the literature and the developments related to the new Rh blood type and to know what information is really fact and which papers are theoretical and often merely confusing. A good review of the subject and particularly of the literature is therefore a great help to any physician with transusions and to obstetricians who may encounter Rh incompatibility as a serious complication of otherwise normal gestation. The new review by Edith Potter fills an important need in medicine. It offers a comprehensive review of the literature up until November 1946 and in general separates the good from the bad in this very much confused field. The chapters on pathology, clinical diagnosis, and course of the disease and the illustrations in the book are particularly worth referring to. The details of postmortem examinations of the newborn can suffer from hemolytic disease of the newborn can not be found in as complete and clear fashion in any other monograph or book on this subject. This volume can therefore be recommended to all readers of *SURGERY GYNECOLOGY AND OBSTETRICS* without reservations regarding it.

LOUIS K. DIAMOND.

THE seventh edition of Buchanan's *Manual of Anatomy* is the American form of the guide which first appeared in 1906. The original work was written by A. M. Buchanan Professor of Anatomy in Anderson College, Glasgow. The current revision is the fourth in the edited series, and the first done by Professor F. Wood Jones and five of his colleagues at the University of Manchester.

SURGERY GYNECOLOGY AND OBSTETRICS

546

The opening chapter deals very helpfully with terminology and topography, the second with development and growth, the third through the sixth with skeletal anatomy. The next six chapters are arranged on regional basis: they present the gross structure of the upper extremity, lower extremity, abdomen, thorax, head and neck. These regional accounts are followed by three sections on the nervous system and the organs of special sense. A serviceable glossary follows, the latter succeeded by the terminal section on biography—offering notes on anatomists whose names appear eponymously in the manual's text.

The regular chapters (i.e. the text material exclusive of glossary, notes, and index) cover more than 1500 pages. They present amply all of the expected information on gross anatomic structure. However the treatment of musculature does not equal that by the late Professor Bardeen in the Jackson edition of the *Morris* the account of the vascular system suffers by comparison with that by Professor Patten in Schaeffer's edition of *Morris' Human Anatomy* (likewise regional in pattern) outranks that of Buchanan's *Manual*.

The book is illustrated with 847 uncolored figures prepared from simple line drawings, and 48 recent photograms. Some of the line drawings, deleted from predecessor editions, have been restored. 180 new drawings of similar character were borrowed from Professor Jones' volumes on the hand and foot. In

the preface, these drawings are described as being "beautiful" as well as clear. That they possess clarity is uncontested; however, were a reviewer carelessly to admit that these illustrations are beautiful, he would be obliged to employ artificially broad terms in describing the eminently better figures of Cunningham's *Text Book and Manual*, those which used to appear in the excellent German editions of the *Spalteholz Atlas*. The pictures of bones—always undramatic—are adequate. The drawings of the muscles are generally satisfactory although those depicting the deep antibrachial muscles, the fascial coverings and compartments of the palm, the synovial sheaths of the extensor tendons, the interosseous hamstrings, and the anterior crural muscles are of the sort that one would expect to find in any ordinary compendium. The portrayal of perineal anatomy is not only poor but incorrect; the pictorial treatment of the inguinal region is stylized, as is that of abdominal, pelvic, and thoracic viscera.

The only essentially new features are the x-ray plates. The text is standard, the numerous descriptive legends are not highly descriptive. However, despite the fact that the volume does nothing novel and discharges its pedagogic obligation without use of distinctive text or of an exceptional series of figures, it might prove a desirable adjunct to a student's or a practitioner's library.

THE TOXEMIAS OF PREGNANCY

With Emphasis on the Present Modes of Therapy

JOHN E. SUMMERS M.D. Goodrich Michigan

IN 1940 The American Committee on Maternal Welfare (20) adopted a new classification of the toxemias of pregnancy attempting to differentiate the conditions which are present before pregnancy occurs but which may be aggravated by pregnancy from those which are initiated by and are peculiar to pregnancy itself. Using this classification of the toxemias of pregnancy Williams and Weiss reviewed 1,790 maternal deaths, finding 318 due to toxemias which they analyzed as follows:

- Group A Diseases not peculiar to pregnancy
- 1 Hypertensive disease (hypertensive cardiovascular disease)
 - a Benign (essential) mild severe 13
 - b Malignant 3
 - 2 Renal disease
 - a Chronic vascular nephritis or nephrosclerosis 10
 - b Glomerulonephritis
 - 1 Acute 3
 - 2 Chronic 10
 - c Nephrosis
 - 1 Acute 1
 - 2 Chronic 0
- Group B Disease dependent on, or peculiar to pregnancy
- 1 Pre-eclampsia
 - a Mild 0
 - b Severe 63
 - 2 Eclampsia
 - a Convulsive 143
 - b Nonconvulsive (that is, coma with post mortem findings typical of eclampsia) 13

From The Goodrich General Hospital.

- Group C Vomiting of pregnancy 37
Group D Unclassified toxemias 13

THE DIFFERENTIAL DIAGNOSIS OF THE TOXEMIAS OF PREGNANCY

Hypertensive and renal disease are usually present before the twenty-fourth week of gestation whereas pre-eclampsia and eclampsia appear after that week (31). Essential hypertension may first become apparent during pregnancy and may subside between pregnancies, at least to some degree (102). If the parturient is seen for the first time during the last trimester with toxemia, a correct diagnosis may be impossible at that time. Postpartum examination of the nephritic individual will show evidence of kidney damage (107) whereas the kidneys of the pre-eclamptic or eclamptic patient rapidly return to normal soon after delivery (31, 94). Albuminuric retinitis, when it occurs, is proof of the existence of chronic nephritis (76) therefore the value of examining the ocular fundi of the toxemic patient is obvious.

Tenny and Parker state that the degree of albuminuria is the most reliable sign as to the severity of the toxemia. Essential hypertension per se causes little if any proteinuria. Sharkey and Hess report 115 cases of essential hypertension complicated by pregnancy of which 52 showed mild albuminuria and 63 showed no albuminuria.

The diagnosis of the type of toxemia present is of some importance. Pregnancy complicating chronic hypertension associated with cardiovascular or renal degeneration offers a bad prognosis for both mother and baby. Intrauterine death

of the fetus is common. If the mother can be carried to the thirty-second week of gestation cesarean section may save the life of the infant. Dieckmann (34) states that 21 per cent of his patients with vasculorenal disease were delivered by cesarean section. Essential hypertension and mild pre-eclampsia offer a good prognosis for mother and baby.

THE INCIDENCE OF THE TOXEMIAS OF PREGNANCY

The incidence of all toxemias of pregnancy from various sources is given as 5 per cent (33) from 5 to 7 per cent (79) from 6 to 9 per cent (28) and 14 per cent (93). The great majority of these toxemias fall in the mild category (25, 32, 44, 45).

TOXEMIAS AS A CAUSE OF MATERNAL DEATH

About 20 per cent of all maternal deaths are due to the toxemias of pregnancy (84, 85). The importance of preventing eclampsia is revealed by the fact that the mortality rate of mild toxemias is practically nil while 'The appearance of convulsions increased the maternal mortality rate almost ten times' (35). It is a well recognized fact that pre-eclampsia has a low maternal mortality rate, while eclampsia carries a very high death rate for both mother and baby (35, 44, 45, 59).

The maternal death rate from eclampsia is reported as being from 10 to 20 per cent (59), 13 per cent (35), 20 per cent (28) and 23.5 per cent (56). In recent years there has been a remarkable decrease in maternal deaths from eclampsia because of conservative treatment superseding operative treatment and accouchement forcé (86). Arnell and Watson have reported 151 consecutive cases of eclampsia without a maternal death, employing 'an ultraconservative plan' of treatment. Cooke has seen 304 cases of eclampsia with only 1 maternal death while Emge wrote me that it has been 10 years and longer since he has seen a death from eclampsia.

THE INCIDENCE OF THE VARIOUS TYPES OF TOXEMIAS (32)

Type	Dieckmann	Seawery	Kallgren
Pre-eclampsia	36%	28%	57%
Vasculorenal disease			
Hypertensive disease	11%	31%	
Nephrosclerosis	%		
Glomerular		7%	
Nephritic, acute	2%		
Eclampsia	4%	4%	2%

To illustrate this decrease in maternal mortality from eclampsia the following is quoted from Eastman and Whitridge:

THE INCIDENCE AND MATERNAL MORTALITY AT JOHN'S HOPKINS HOSPITAL, 1896-1941

Period	Method of treatment	Cases	Maternal
1896-1905	Prior to 1912 therapy was governed by the belief that immediate delivery was imperative. Consequently no cesarean section forcé.	32	25
1906-1915	Mildness of the toxemia and conservative treatment were the favored procedure of that time.	51	25
1916-1925	An effort to be more conservative developed, but if the case was severe, radical operative delivery was effected.	39	11
1926-1935	A modified Strout's regime—no accouchement forcé, the occasional use of cesarean section.	127	15
1936-1941	Conservative treatment individualized. Free, liberal use of hypotensive drugs intravenously.	99	1

Novy reviewed 115 cases of eclampsia treated prior to 1932 by cesarean section and accouchement forcé, with a mortality rate of 23.5%, and 59 cases treated between 1930 and 1938 by bedrest, rest, isolation, and hypertonic glucose given intravenously with a mortality rate of 5.1%.

THE EFFECT OF TOXEMIA OF PREGNANCY ON THE FETUS

Brown, Lyon and Anderson state that 5 per cent of normal white mothers have premature deliveries, and 7 per cent of those with mild toxemia, 27 per cent of those with severe toxemia, and 38 per cent of those with eclampsia have premature deliveries.

Davis reviewed 642 consecutive premature deliveries. She found 'Although toxemias are a major cause of prematurity, they are so likely because of their associated high incidence of induced or artificial delivery before term, intrauterine death of the fetus, premature separation of the placenta, hydramnios, and twins. The toxemias of pregnancy were associated with 30.7% of the dead born, macerated group. Of the various types of toxemias, renal disease had the highest fetal mortality rate, 30.3 per cent, and the lowest fetal survival rate 48.5 per cent.'

Eastman and Steptoe record a decline in fetal mortality at The Johns Hopkins Hospital as follows:

	Maternal Deaths	Fetal Deaths
1924-1928	11 0%	40 10%
1929-1943	5 7%	30 1%

history and urinary findings are usually sufficient. Albuminuric retinitis, when present, is positive proof of the existence of chronic nephritis (74).

The deleterious effect of this disease upon the mother and fetus has already been shown (26, 28, 100, 115, 124). It is best, in proved cases, to empty the uterus by dilatation and curettage, by rupture of the bag of waters, or if the fetus is viable, by induction of labor or cesarean section (21, 25, 28, 45, 81, 100). The patient should be sterilized (28, 34).

DISEASES DEPENDENT ON OR PECULIAR TO PREGNANCY

THE CAUSE OF THE TRUE TOXEMIAS OF PREGNANCY

A great many theories have been advanced in the past as to the cause of the toxemias of pregnancy (31, 116, 64) but its cause is still unknown. Vasospasm, and sodium and water retention are believed to cause the disease (25, 28, 30, 36, 35, 31, 43, 44, 51, 57, 59, 77, 84, 82, 105, 106, 111, 121, 125). Associated factors are primiparity, multiple pregnancy, hydatidiform mole, and hydramnios (18, 28, 32, 59, 107).

Goldblatt clamps applied to the renal arteries of pregnant dogs and rabbits produce within 48 to 120 hours, after a relatively slight constriction weakness, basitude, hypertension, convulsions, albuminuria, and nitrogen retention (18). However pregnancy occurring in experimentally made by pertensive rats (89) and dogs (22) causes a fall in the blood pressure to normal.

Pyelitis of pregnancy does not cause toxemia. Mussey and Lovelady at the Mayo Clinic reported 117 cases of pyelitis of pregnancy, only 3 of which developed toxemia of pregnancy. Among 163 cases of toxemia there were only 6 cases of pyelitis of pregnancy (83).

Fuster has produced eclampsia in a nontoxicemic primigravida by the intravenous infusion of 800 c. c. of a 10 per cent solution of saline.

Restriction in weight gain is very important during pregnancy. Odell Lester and Mengert found that of 641 women who weighed over 200 lb. before delivery, 31.4 per cent had toxemia of pregnancy. Other complications of pregnancy and delivery occurred more frequently in this group of obese patients. Loughran reviewed the records of 325 women who had been placed on a high protein, low carbohydrate, high vitamin diet and whose weight gain during pregnancy had been kept below 20 lb. Any edema developing during the last part of pregnancy was treated by increasing the protein intake and decreasing the salt in the diet. These women all fared better than the aver-

age and had remarkably short labors. Lusk advises that the weight gain during pregnancy be restricted to 16 pounds as a maximum, or not more than 2 pounds in any month. He presented 1000 patients, who were of normal weight at the beginning of pregnancy and whose weight gain during pregnancy had been restricted to 16 pounds. They had been given a high protein, high vitamin, low salt diet with salt restriction if edema developed. In this group there were no toxemias, no maternal deaths, a gross fetal mortality of 21 per cent, and an average birth weight for all babies of less than 7 pounds. Others (27, 35, 94) emphasize the need of restricting the weight gain of the normal woman during pregnancy to less than 20 pounds.

Parks (91) believes that the normal sodium and potassium ratio is upset by an excess of adrenocortical hormone, and suggests that the fetal adrenal glands contribute to this excess.

Toxemia is of frequent occurrence in pregnancies complicating hyperthyroidism (61). Various hormonal imbalances are being postulated as causing toxemia (105, 111) but are still speculative (92). Snyder has produced toxic abortion of the placenta in rabbits by the injection of sodium 5. The frequent occurrence of toxemia in association with hydatidiform mole (18) tends to support the opinion of those believing in an endocrine imbalance as the cause of toxemia of pregnancy.

THE PATHOLOGY OF TOXEMIAS OF PREGNANCY

The patient may injure herself during a convulsion, fracture and dislocation of both shoulders having been reported (23). Aspiration of food, mucus, food, and medicine may cause death (4). Irving (59) states that the most common cause of death is acute cardiac dilatation. Teel, Reid and Hertig state that 30 per cent of all eclamptic patients develop acute pulmonary edema. Cerebral hemorrhage (56, 93) and abortion (60) may occur. Cerebral edema is common (4).

At autopsy there is no pathognomonic lesion (1). Arteriole necrosis and hemorrhages are found in most of the organs (59, 63). Page and Cox in 24 selected autopsies following toxemia of pregnancy found a nonspecific thickening of the glomerular membranes in the kidneys.

Abruptio placenta occurs frequently (16, 32, 117) while placenta previa occurs rarely (117). There are no characteristic infarcts seen in the placenta (55, 103).

PRE-ECLAMPSIA

Pre-eclampsia is a disease peculiar to pregnancy developing after the twenty-fourth week of ges-

The future of the pre-eclamptic patient Dexter Weiss, Haynes, and Sisc state that improvement begins within 12 to 24 hours postpartum, and is associated with diuresis and loss of edema. Taylor, Warner and Welsh state that the sodium and water retention occurring during pregnancy is related to the concentration of estrogens in the body and that normally a puerperal diuresis results post partum.

According to Peckham the pre-eclamptic patient recovers within 10 to 14 days postpartum but of 343 women followed up after delivery, 40 per cent showed some sign of chronic nephritis. Browne and Dodds (14, 15) found that 50.9 per cent of pre-eclampsics have some residual hypertension. Cosgrove and Chesley, reviewing 1,615 cases of toxemia, found that the incidence of remote permanent hypertension was 53 per cent. Eastman and Steptoe show that the duration of the pre-eclampsia has a direct relationship to the persistence of hypertension postpartum.

Duration of pre-eclampsia (weeks)	Total No. patients	Per cent of residual hypertension
1-4	8	16.8
5-6	47	30
7-8	6	38.9
9-10	11	55.6
11-12	54	70.8

Irving (59) gives the incidence for postpartum hypertension as 21 per cent for mild pre-eclampsia and 4.8 per cent for severe pre-eclampsia. Others (30) also believe that severe pre-eclampsia has a better late prognosis than mild pre-eclampsia. Ryland thinks that this may be due to the tendency to terminate the pregnancy early in the severe cases.

On the other hand, Miller (77) states that 100 patients were carefully studied for 1 or more years after an attack of toxemia and no evidence of significant vascular or renal morbidity was found in those who were known to be normal prior to their abnormal pregnancy.

The advisability of future pregnancies depends upon the amount of permanent damage sustained by the vascular and renal systems (99).

ECLAMPSIA

According to Stander (108) the typical clinical and laboratory findings of eclampsia are: by pertension, albuminuria, edema, convulsions, elevated blood uric acid and decreased CO_2 combining power, decreased uric acid clearance and decreased urinary output, followed by a complete return to normal after the eclampsia.

The convulsions of eclampsia are indistinguishable from those of epilepsy (59). Convulsions occurring during pregnancy may be due to causes other than eclampsia. Arnell (5) states that of 162 pregnant women with convulsions admitted at the Louisiana Charity Hospital only 120 had eclampsia. The other 42 patients were diagnosed as having epilepsy, central nervous system affections, hysteria, diabetes, drug reactions, blood diseases, hypertensive encephalopathies, chronic renal disease, food poisoning, hyperemesis gravidarum, chorea, tetany and alkalosis.

Most cases of eclampsia are preceded by pre-eclampsia but the onset of eclampsia may be so abrupt that the prodromal signs and symptoms may be missed unless the parturient is seen weekly during the last trimester of pregnancy (45). Stander (108) reviewed 34 cases of postpartum eclampsia and found that 13 of the patients had had no antecedent toxemia.

Eastman and Whitridge state that the approach of eclampsia is heralded by

1. Severe, continuous headache
2. Swelling of the face or fingers
3. Dimness or blurring of vision
4. Persistent vomiting
5. Decrease in urinary output
6. Epigastric pain (a late symptom)

Eclampsia may be mild or severe. Dieckmann (31, 33) gives the criteria for severe eclampsia as

1. Coma
2. Temperature of 102° F or more
3. Pulse rate over 120/min.
4. Respiratory rate over 35/min
5. More than 10 convulsions
6. Cardiovascular impairment (edema of the lungs, persistent cyanosis, low or falling blood pressure, low pulse pressure)
7. Failure of treatment to
 - a. Stop the convulsions or prevent their recurrence
 - b. Produce a urinary output of at least 700 c.c. per 24 hours
 - c. Prevent the onset of or increase in degree of coma
 - d. Produce a dilution of the blood as indicated by a decrease of at least 10 per cent in hemoglobin, cell volume, or serum protein concentration

The incidence of eclampsia. Eclampsia occurs once in 500 to 800 deliveries (107, 108). Eclampsia may occur antepartum, intrapartum, or postpartum. Intercurrent eclampsia indicates a situation in which pregnancy continues for a period of time after the eclamptic patient has ceased to have convulsions (6).

INTERNATIONAL ABSTRACTS OF SURGERY

or if the cervix is not "ripe" cesarean section under spinal or local anesthesia.

Cook terminates the pregnancy if the disease is progressing. Otherwise, he waits until the fetus is mature, then interrupts the pregnancy, thus because of the rather frequent death of the fetus in utero if allowed to go to term and to reduce the damage to the kidneys which occurs steadily in prolonged cases.

Congrove and Chesley state "Thus it can very definitely be stated that prompt termination of the pregnancy in the presence of established toxemia after the thirty-fourth week of gestation serves alike and directly both the maternal and the fetal interest. It also serves to prevent fixed hypertension as a sequel of the toxemia. They recommend medical induction augmented by stripping and rupture of the membranes. In the presence of fulminant progress of the case toward ex- plosive eventuality cesarean section for delivery should be unhesitatingly resorted to."

Danforth writes that if the pre-eclamptic patient does not improve on treatment the pregnancy should be terminated. If the cervix is partially effaced with some dilatation, the membranes are ruptured if closed with no effacement, a cesarean section under local anesthesia is considered.

Dickmann (32-35) usually attempts to carry the toxemic patient to the period of viability of the fetus, to the thirty-second week of gestation. If the cervix is "ripe" the membranes are ruptured. If contractions have not begun within 12 hours after rupture of the membranes, 1 minim dose of pitocin are given every 30 minutes until labor has begun. If the cervix is unsuitable for this, a cesarean section under local anesthesia is done. He (34) delivered 11 per cent of his pre-eclamptic patients by cesarean section.

Eastman and Steptoe emphasize that prompt delivery of the pre-eclamptic patient is advisable to prevent eclampsia and the development of permanent, residual, hypertension. In 85 per cent of 510 patients with pre-eclampsia who were not in labor on admission, termination of the pregnancy ensued within 5 days in the following manner:

- 1 Spontaneous onset of labor 185 CASES.
- 2 Artificial rupture of the membranes 143 CASES.
- 3 Medical induction 37 CASES.
- 4 Cesarean section 66 CASES.
- 5 Hysterectomy 4 CASES.
- 6 Vaginal abortion 1 CASE.
- 7 1 CASE.

The incidence of cesarean section for delivery in cases of pre-eclampsia has risen from 3.0 per cent in the period from 1924 to 1928 to 6.6 per cent for the period from 1939 to 1943.

Falls, in the discussion following Haber's and Arnell's papers, stated that he had performed cesarean section in 49 cases of fulminating pre-eclampsia without a maternal death.

Irving (59) states that the pregnancy should be terminated if the patient fails to improve or if the disease progresses. Thirty-six per cent of his cases of severe pre-eclampsia were terminated in the following ways:

- a By rupture of the membranes. 23 per cent
- b By cesarean section 8 per cent
- c By other methods 5 per cent

Miller (77) states "When there is no improvement after a reasonable trial with these measures, usually one week to ten days, pregnancy is terminated by the most conservative method. This may mean medical induction, using pitocin instead of pituitrin, or rupture of the membranes. A few cases have been bagged and rarely cesarean section has been resorted to. In the last few years bagging has practically dropped out of the indications other than the toxemia, for example, cephalopelvic disproportion, previous cesarean section, placenta praevia, and other similar conditions."

Montgomery (80) treats the pregnancy similarly in the severe pre-eclamptic and the eclamptic patient. "If the patient fails to improve with this regime within 48 to 72 hours, or if she has reached the period of maximum improvement over a period of 2 or 3 weeks and begins to show recurrence of toxemia with increase of blood pressure and edema, we terminate the pregnancy by induction of labor in multiparous patients, or, more frequently by cesarean section in the primigravida."

Munsey and Hunt list the termination of pregnancy in 216 cases of toxemia of pregnancy treated at the Mayo Clinic between 1931 and 1939 as follows:

Means of delivery	No. of mothers	No. of babies	Per cent of total deaths
Spontaneous			
Medical induction	109	113	75.8
Medical induction failed	37	37	24.2
Spontaneous onset			
Medical induction failed, Artificial rupture of the membranes	9	9	10
Artificial rupture of the membranes	10	10	10
Bag induction	21	21	10
Cesarean section	14	16	33
Total	166	161	77.1

TABLE I.—ESSENTIAL DRUGS AND DOSAGES RECOMMENDED FOR ECLAMPSIA

Author	Sedatives	Magnesium sulfate	Hypertonic glucose
Allen ()		c. 5 per cent solution after first fit Repeat 5 c. I.M. after each fit until controlled.	1000 c.c. of 50 per cent I.V. or 3 times daily. From 500 to 400 c. of 50 per cent or from 100 to 200 c.c. of 30 per cent to stimulate diuresis.
Arnall (5)	Morphine sulfate (gr. 5/6) and sodium phenobarbital (gr. 5) hypodermically. If fits persist give from 3 to 6 gr. of sodium amylal I.V. or repeat the magnesium sulfate. After the attack give sodium phenobarbital (gr. 1/4 to 3/4) 3 to 6 hrs.	5 minutes later if fits are still present, give 50 c. per cent I.V. Repeat if fits recur.	500 c. of 50 per cent solution I.V. stat. and during delivery. If heart failure de- velops, 500 c. of 50 per cent, or from 50 to 100 c. of 50 per cent solution I.V.
Boston City Hospital ()	Sodium luminal (gr. 1 to 5) I.M. q. 4 hr. p. a. Paraldehyde per rectum, 1 dr. in oil. Pentothal I.V. to control fits.		100 c.c. of 50 per cent or 200 to 400 c. of 30 per cent solution I.V. or 3 times daily.
Cooke ()		gr. I.V. q. 3 hrs. until fits are controlled.	From 50 to 100 gr. in 5 or 10 per cent solution I.V.
Crofters & Chesley (5)	Morphine sulfate, (gr. 5/6) dose.	50 of 50 per cent solution q. 4 hr. as long as fits persist. Dose q. 4 hr. times after last fit, I.V.	500 c. of 5 per cent solution I.V. q. 4 to 6 hours.
Dandforth (27)	Morphine sulfate (gr. 1/6) hypo. stat. and q. to 4 hr. until fits cease or respira- tions drop to 12/min. Luminal sodium, (gr. 2) p. a.	50 of 50 per cent solution I.M. stat. c. after each fit. Not more than 50 c.c. in 24 hrs.	From 500 to 1000 c. of 50 per cent solu- tion I.V. q. 4 hrs.
Dickson (33) (35)	Luminal sodium (gr. 1) hypo. q. 6 to 12 hr. Chloral hydrate, grs. 10 to 20 c. starch water q. 6 to 12 hrs per rectum.	6 c.c. of 50 per cent solution I.M. stat. and after each fit.	1000 c. of 50 per cent solution I.V. q. or 3 times a day. From 100 to 500 c. of 30 per cent solution for heart failure.
Eastman (43) (44) (45) (46)	50 of paraldehyde per rectum stat. All eclampsias at	50 of 50 per cent solution I.M. and re- peat every 6 hrs.	100 c. of 5 per cent solution I.V. q. 4 to 6 hrs.
Hanley (33)	Chloral hydrate (gr. 50) and sodium bromide (gr. 60) per rectum.	50 c.c. of 50 per cent solution stat. and q. 4 hr. until fits stop. Not to exceed 20 in 4 hrs.	500 c. of 5 per cent solution I.V. to 4 times daily.
Huber (56)	Sodium amylal (3 1/4 to 7 1/2 gr.) I.V. q. 5 to 6 hrs.	50 of 5 per cent solution I.M. after each fit.	From 1000 to 2000 c.c. of 50 per cent solution I.V. or 3 times daily. Use 50 or 100 per cent solution for heart failure.
Irving (39)	Morphine sulfate, (gr. 1/6) hypo. or pa- raldehyde, dr. 5 in oil per rectum.	From 10 to 50 c. of 50 per cent solution I.M. q. 4 to 6 hrs.	50 c. of 5 per cent solution I.V. q. 4 to 6 hrs.
Give 5 minims of veratrum viride (veratrine) hypodermically on admission. Repeat p. a. 1 to 2 minute intervals 1/2 to 2 minims doses to keep the blood pressure below 90 systolic and pulse below 80/min; repeat if another convulsion occurs.			
Miller (77) (78)	Morphine sulfate to control fits. Bar- biturates I.V. as an alternate.		From 250 per cent solution I.V. if there is no pulmonary edema.
Montgomery (80)	Morphine sulfate (gr. 1/6 to 1/4) hypo- dermally; Chloral hydrate (from 50 to 40 gr.) per rectum; also barbiturates.	5 c.c. of 50 per cent solution I.V.	50 per cent solution I.V.
Mossey and Mossey (84)	Heavy sedation with morphine sulfate and pentobarbital (gr. 4), I.V.		Yes
Oldham (88)	Sodium amylal (gr. 1/4) I.M. As last resort, ether in oil per rectum.	5 c. c. of 5 per cent solution I.M. and repeat to control fits.	100 c. c. of 50 per cent solution I.V. and repeat if coma persists. 500 c. c. of 50 per cent solution.
Smell (90)	Morphine sulfate (gr. 1/6) q. 1 hr. until fits are over or respirations fall to 15/ min.	50 of 10 per cent solution I.V. and also I.M. 50 p. a. for fits. Not more than 80 c.c. in 24 hrs.	From 500 to 1000 c. of 50 per cent solu- tion I.V. From 100 to 500 c. of 50 per cent solution or 3 times daily.
Woodward (96)	None	10 of 50 per cent solution I.M. stat. and 3 c.c. q. 6 hrs.	500 of 10 per cent solution plus 50 c.c. of 50 per cent solution I.V.

Veratrum hypodermically (minims 3 to 5 or more) q. 1 to 3 hrs. to keep blood pressure below 120/90 and pulse rate below 80/min.

I.M. means intramuscularly
I.V. means intravenously

In 1945 Arnall (5) reported 142 cases of eclampsia treated by an ultraconservative method without a maternal death. The pregnancies were terminated in the following ways (See table at top of page 322)

Later in 1945 Arnall and Watson reported 151 cases of eclampsia, treated in a similar manner as the previously mentioned 142 cases, without a maternal death. This last report included 52 cases of intercurrent eclampsia. Intercurrent eclampsia is

The incidence of the various types of eclampsia as given by Greenhill (52) Arnell (5) Irving (59) and Whitacre (121) is given below

Author	Antepartum per cent	Intrapartum per cent	Postpartum per cent
Greenhill	20	30	50
Arnell	14	21	65
Irving	20	5	5
Whitacre	77	6	17

Postpartum eclampsia occurs most frequently during the first day of the puerperium but may occur as late as the eighth day following delivery (108).

In 1945 Arnell and Watson reported 53 cases of intercurrent eclampsia without a maternal death, the largest series on record.

The Treatment of Eclampsia The modern treatment of eclampsia is medical for reasons already cited. Stroganoff (109, 110) introduced the conservative treatment of eclampsia. Titus (115, 116) introduced the intravenous use of hypertonic glucose, and Lazard the intravenous use of magnesium sulfate. Bryant and Fleming developed the use of veratrum viride in the treatment of eclampsia. Hypertonic glucose solutions given intravenously and magnesium sulfate given intravenously or intramuscularly usually with morphine sulfate or a barbiturate, are employed by most workers in the treatment of eclampsia (2, 6, 7, 8, 9, 11, 12, 21, 25, 35, 45, 53, 59, 67, 74, 84, 88, 100, 121, 126). Some include veratrum viride in combination (51, 59, 63) (96, 121, 126). Paraldehyde is used as the principal sedative by others (12, 40, 41, 59, 63). A few workers recommend venesection when pulmonary edema develops (25, 48, 49, 77, 109, 110).

The Stroganoff (109, 110) method for treating eclampsia, in use at the present time by Kampermann and Seeley Falls, and in a more or less modified form by Stander, Titus (115, 116), Mengert and Sage, consists of the following:

1. Morphine sulfate (gr $\frac{3}{4}$) given hypodermically.
2. Chloral hydrate (from 20 to 40 gr) per rectum 1 hour later.
3. Morphine sulfate ($\frac{3}{4}$ gr) hypodermically 3 hours later.
4. Chloral hydrate (30 gr) per rectum 4 hours later.
5. Chloral hydrate (from 15 to 30 gr) per rectum 6 hours later.
6. Chloral hydrate (20 gr) per rectum 7 hours later.

The chloral hydrate is dissolved in 4 or 5 oz. of warm water and slowly injected into the rectum, the patient being given light chloroform anesthesia to prevent a convulsion which might result from the local irritation. The opportunity is used to make a rectal examination to determine the progress of labor. The patient is kept in a dark room and watched carefully. Chloroform is used to control the convulsions. If the convulsions are violent and numerous, the membranes are ruptured and venesection is performed. After recovery the patient is given from 5 to 10 gr of chloral hydrate orally t.i.d. for 3 days.

Inasmuch as Arnell and Watson have reported "151 consecutive cases of all varieties of eclampsia without a maternal death, a detailed study of their regime for the treatment of eclampsia would not be amiss. They (5, 6) attribute their success to the following features:

1. An ultraconservative concept of management (do not overtreat).
2. Constant care by a trained physician.
3. Individualized regimen.
4. Frequent change of posture, oxygen, aspiration of mucus, and an hourly observation of the urinary output by means of a retention catheter.
5. Limitation of sedation to control the fits.
6. Limitation of intravenous glucose therapy just sufficient to maintain the urinary output, return to oral glucose therapy as soon as possible.
7. Delayed delivery until recovery occurs.
8. Induction of labor by the simplest method.
9. Minimal operative procedures, local anesthesia.

The workers using the Stroganoff regimen for the treatment of eclampsia or a modification of it have already been mentioned. Stander (63) (107) (108) at the Cornell Medical School uses a modified Stroganoff regimen, laying emphasis on the treatment of any existing acidosis with sodium lactate, the intravenous use of glucose to protect the liver and to stimulate the urinary output, and conservative treatment of the pregnancy. Barbiturates are being used instead of chloral hydrate.

The recommendations of other workers for the treatment of eclampsia are given in Table 1 on page 321.

The treatment of pregnancy in eclampsia. The Stroganoff method of treatment of eclampsia entails expectant treatment of the pregnancy (4, 75, 99, 107, 109, 110, 115, 116). The bag of waters may be ruptured if the eclampsia is progressive.

Teel and Reid (112) found an incidence of hypertonism of 10.3 per cent in patients who had eclampsia and who were known to be normal before the attack

VOMITING OF PREGNANCY

Approximately 50 per cent of pregnant women develop some nausea and vomiting during the first trimester of the gestation. This usually subsides but may become pathologic and progress into hyperemesis gravidarum (28). It is, therefore, important to treat all of these mild cases of nausea and vomiting to prevent progression into the pathological state.

The cause of the nausea and vomiting of pregnancy is not known. Symptomatic treatment is usually effective. Rest, relief from household duties, abstinence from sexual intercourse, avoidance of tobacco smoke and unpleasant odors, sedatives and frequent small feedings high in carbohydrate content usually suffice (39). Vitamin B₆ (pyridoxine hydrochloride) has been reported as being very beneficial (42) (104) (118) although it has been the opinion of other authors that it is valueless (54).

Progression of the disease necessitates hospitalization and the institution of a strict program of rest, isolation, sedation, and intravenous feedings. Psychiatric help is often very beneficial (21) (39) (54).

Cosgrove and Carter (24) state that they treated 300 cases of hyperemesis gravidarum over a 10 year period with no deaths and had to perform only 1 therapeutic abortion.

SUMMARY

A review of the present concept of the toxemias of pregnancy and the methods of treatment in vogue at the present time is given. Vasospasm and sodium and water retention are characteristic features of the disease. Mild pre-eclampsia and essential hypertension carry a good prognosis for the mother and child, but severe cardiovascular, renal disease and chronic nephritis carry a bad prognosis for them. A patient with severe pre-eclampsia should have her pregnancy terminated, preferably after the fetus is viable, and the method of termination should depend upon the state of the cervix.

Cesarean section is being employed more frequently as a means of delivery in the patient with severe pre-eclampsia. Once eclampsia has supervened the best results are obtained by treating the eclampsia medically and the pregnancy expectantly.

Method of delivery	Type of eclampsia			Percent of total no. of cases
	Ante-partum no. of cases	Intra-partum no. of cases	Post-partum no. of cases	
Vaginal delivery	7	5	37	53.7
Spontaneous delivery	6	6	20	26.6
Forceps delivery	1		6	
Breech extraction				
Version and extraction				
Embryotomy				
Abdominal delivery	3	5		6.3
Cesarean Section	3	3		
Cesarean Section and Hysterectomy				

defined as that type in which delivery did not occur for 3 or more days after the cessation of convulsions.

The methods of delivery in these 52 cases of intercurrent eclampsia are listed as follows:

Method	Time interval in days				Percent of total
	to 1	4 to 7	8 to 10	Over 10	
Cesarean section					1.6
Vaginal delivery		14			96
Spontaneous delivery	10	20		13	54.6
Forceps delivery					
Breech extraction					
Version and extraction					
Embryotomy					
Total		14	2	2	100

At the Boston City Hospital (11) it is recommended that the pregnancy be terminated after the convulsions are controlled, vaginally if possible, but by cesarean section if vaginal delivery appears to be a prolonged affair. Cooke, at the University of Texas, terminates the pregnancy after the patient is in good condition, cesarean section being used mostly on obstetrical indications. He has treated 204 cases of eclampsia with only 1 maternal death. Cosgrove and Chesley at the Margaret Hague Maternity Hospital, allow the pregnancy to proceed until the patient is in good condition when labor is terminated, preferably by medical induction. Danforth recommends that the pregnancy be treated expectantly. Dieckmann (32-35) at the University of Chicago ruptures the membranes if the patient is in labor; if the patient is not in labor the pregnancy may be terminated after 8 to 12 hours by the induction of labor or

rarely by cesarean section under local anesthesia for the progressive eclamptic patient. Eastman (44, 45-63) at Johns Hopkins University treat the pregnancy expectantly. Irving (59), of Harvard University, terminates the pregnancy within 24 to 72 hours, only after the convulsions have ceased. If the cervix is soft and dilating the membranes are ruptured. Miller (77-78) of the University of Michigan, states "After a few days when the patient's condition has definitely improved, pregnancy is terminated by inducing labor."

We do not subscribe to the idea of curing these patients for any protracted period of time after a convulsive seizure. He states that the pregnancy was terminated in 224 toxic patients in the following ways:

1. Spontaneous delivery in 63 per cent.
2. Thirty-seven per cent were terminated usually by medical induction (53%) or rupture of the membranes (14%).
3. Cesarean section was carried out in 44 per cent (10 patients) but the indications were primarily for reasons other than toxemia.

Musey and Musey (84) of the Mayo Clinic induce labor by medical induction or rupture of the membranes after the convulsions are controlled. Woodward at the University of Cincinnati, terminates the pregnancy expectantly. Allen, at Washington University, Falls (48) at the University of Illinois, Hanley at the Los Angeles County Hospital, and Montgomery (80) at the Jefferson Medical School, incline toward operative intervention if the eclampsia is progressive.

The future of the eclamptic patient. Arnold and Watson reported that of 38 patients followed from 6 months to 5 years after an attack of eclampsia, only 3 showed any abnormality. The abnormality noted was elevation of the blood pressure above 140/90 mm. Hg. and this was regarded as being due to essential hypertension.

Cosgrove and Carter (24) found that of 153 patients who had had eclampsia and were followed up for 8 years after the attack, 90 had 143 subsequent pregnancies and only 2 of these had eclampsia again.

Irving (59) states that about 10 per cent of the eclamptic patients who were normal before the attack of eclampsia developed a subsequent hypertension and about 4 per cent had another attack of eclampsia in a subsequent pregnancy.

McClellan, Strayhorn and Densen (74) reviewed 75 cases of eclampsia, and 30 of the patients were observed from 6 months to 13 years after the attack. In 32 subsequent pregnancies occurring in this group there was no recurrence of eclampsia.

Savittali M.: The Treatment of Progressive
Phthalamus. A. 047 33 214

The author reports a case of so-called malignant phthalamus with severe intra then symptoms slight and in a mal vol n of the cases there were pregnancy in another occurred following a twin a tuberculous infection in the patient the con dition toll and se r m n t a l t r a u m a. Definite myxedema was present in case Th aphthalamus increased in all pat nt ther d rectly after thyroid ectomy several month later Th thyroidect my patient would seem to be a u o f t p r o g r e s s i v e aphthalamus.

In the patient with myxedema thyroid medication proved helpful. A a t t a i n m e n t o v e r t h e p i t u i t a r y w a h e l p f u l i n n m i d a s e. In a more severe case the condition appeared to be a t a l b e p u r e x-ray therapy and a NaCl per alutal lec representation was performed immediately. The patient recovered.

It is emphasized that this subject may should be a mild unless there is a symptom demand it. When r p e n t h i s d t a l d t h o u d b e p u r e s e b e l. X-ray treatment over the pituitary gland and in severe cases if necessary for the prevention of a m i t a l d e c o m p e n s e m a y b e c a r r i e d o u t.

Davidson, A.: Primary Lipid Dystrophy of the Cornea. Arch Ophth. Chic. 017 37 433

The author reports a case of primary lipid dystrophy with a associated hyperbosteremia. The patient at a 6 year old girl had had repeated attacks of pain in the eye and injection of the conjunctiva at intervals of about 3 months first in his left eye and then in both eyes. He had noted smoky opacity in the posterior layer of right cornea. A small area just in the lower part of the right cornea. It was a white area appearing immediately in front of December. The half thickness. There were tiny glitt gold particles in this area. There was little opacification there were no keratic precipitates. In the left eye there were a yellowish white vascularized corneal c. apparently large layers and almost completely covered except for a small area. There above and

small chalklike deposits at various depths of the stroma. There was a constant progression of the opacities in both eyes. The serum cholesterol level from 225 to 390 mgm. per 100 c.c., and a roentgenogram of the skull was negative.

A corneal transplant which was done on the left eye quickly became vascularized and opaque. Sections of the disc which were removed from the cornea showed normal epithelium, considerable vascularization and an incomplete Bowman's membrane. There were focal accumulations of macrophages with no lymphocytes. Large and small globules of fat were numerous both extracellularly and within the macrophages. Later, the cornea about the transplant showed a definite clearing and it was thought that this peripheral clearing might be the cause of the primary lipid dystrophies. The retinoblastic lesion is obscure but other cases with high blood cholesterol have been reported.

ROBERT H. JORDAN, M.D.

Leopold J. H., and Adler F. H.: The Use of Frozen-Dried Corneas as Transplant Material. J. Clin. Ophth. Chic. 1947 37 243.

The authors have carried out experimental work with frozen-dried corneal tissue in rabbits. The technique employed is described, as well as the method of freezing and rehydration. Of the 73 frozen-dried corneas used as transplants, 50 takes resulted. Of the 50 takes, 10 grafts showed corneal vascularization and 9 showed persistent corneal edema. The other 35 corneas showed no serious complication. In 7 of the 30 eyes that received fresh corneal tissue for transplants the cornea healed in place and remained transparent for the 6 month period of observation. Results indicated that frozen-dried corneas may be transplanted into normal rabbit eyes without producing unusual host reaction. It would appear that the chief cause for failure to regain transparency in the rehydration process.

HUGH H. ROWLAND, M.D.

Eight eyes were injected with commercial penicillin of which 4 were sectioned. In only 1 of these had infection been experimentally introduced. In all of the cases the fundi were damaged. There were pigmented changes which in 1 case progressed to retinitis proliferans. There was a tendency toward vascular proliferation and retinal hemorrhages. Similar but less marked changes were found with crystalline penicillin and there seemed to be no predilection for the vascular system as with the commercial preparation.

Sodium sulfacetamide was injected into 16 eyes. The maximum effect appeared only after a delay of several weeks but there was a destructive effect on the retina at the level of the rod and cone layer. One eye receiving a double injection showed retinal detachment and cystic formation within the retina. The damage in all of the cases was more extensive than when crystalline penicillin was injected.

Marfanil caused marked constriction of the retinal vessels and there was marked disturbance in the rod and cone layer.

There was also marked retinal destruction in 9 eyes in which V 335 was injected. In this instance the choroid also seemed to be largely affected but with the other material used it seemed to be only slightly involved.

A further study was made of the diffusion of drugs within both normal and infected eyes following intravitreal injection. In the infected eyes virulent hemolytic streptococci were injected all untreated cases resulting in vitreous abscess and an opaque vitreous. When penicillin was injected up to 6 hours after inoculation it prevented the development of infection, but it had no effect when infection was delayed for 24 hours. Sodium sulfacetamide prevented infection in some cases and merely delayed it in others. Favorable results were obtained with marfanil and V 335 but because of their toxic effects on the eye their action was not fully studied.

In spite of the toxic effects the authors believe that when an eye is endangered by a severe vitreous infection the use of pure penicillin by injection into the vitreous may be justified but the use of the other substances studied seems to be contraindicated because of their severe toxic effects.

WILLIAM A. MAW M.D.

Gordes F. C.: Types of Congenital Cataract. *Am J Ophth.* 947 30 397

As the third Gifford Memorial Lecture, Cordes has offered a systematic discussion of the various forms of congenital cataract. It is well known that certain forms have a hereditary tendency primarily of the dominant type but various types may appear in the same family. Other ocular abnormalities occur in about 50 per cent of the cases of congenital cataract, including strabismus, amblyopia, nystagmus, aniridia, choroidal and retinal changes, and microphthalmos.

There appears to be a definite hereditary tendency in the following types of cataract: congenital total

cataract, lamellar cataract, embryonal nuclear cataract, coralliform cataract, spear cataract, floriform cataract, anterior axial embryonal cataract, anterior and posterior polar cataract, axial fusiform cataract, stellate cataract, and disc shaped cataract.

Blomicroscopy of the lens is important in the localization of the lens opacity, which in turn reveals the time of onset of the opacity. For practical purposes the zones recognized are the embryonal nucleus (lying between the Y sutures) the portion of the lens formed before the third month, the fetal nucleus surrounding the first zone and formed in intrauterine life after the third month, the adult nucleus formed during adolescence and early adult life, and the cortex, the fibers of which are laid down in later life.

Intrauterine trauma may sometimes produce lens opacities, as seen in the reduplication cataracts. It is also known that interference with calcium metabolism and parathyroid secretion as well as avitaminosis will cause lens changes.

There has been considerable attention of late to congenital cataract following rubella in the mother during pregnancy. Sections of an eye with cataract in a 7 weeks embryo with a history of rubella in the mother during the fifth week of pregnancy indicates that the damage is done at the time of the infection.

It is emphasized that the lens is transparent in its normal development and that all congenital lens opacities are pure aberrations and not arrests.

WILLIAM A. MAW M.D.

Bakker, A.: The Action of the Sulfanilamide on Rabbit Lenses in Vitro. *Brij J. Ophth.*, 1947 31 216.

Some years ago the author demonstrated that the perfusion culture method of de Haan kept alive rabbit lenses in vitro for many days. He has now utilized this method for the study of the toxic action of chemicals on the lens.

A concentration of 20 mgm. per cent of sulfanilamide had no noxious effects on the lenses of a 7 weeks old rabbit, and after 3 days in the culture vessel the lenses were quite clear. When the concentration was raised to 400 mgm. per cent however the lenses of a 4 weeks old rabbit became quite opaque within 4 hours. Within 15 hours letters on an underlying paper could no longer be read. After 3 days the experiment was stopped. The opacities were chiefly in the posterior cortex although some were found in the anterior cortex. The lenses contained 385 mgm. per cent of sulfanilamide which shows that the capsule is freely permeable to this drug. The toxicity of the substance was much less marked when the lenses of adult rabbits were used and it required 5 days with a concentration of 400 mgm. per cent to produce some opacities.

The concentration of sulfanilamide required to produce the lens opacities is much above a normal therapeutic dose yet the author believes that some caution is advisable in use of the drug. A case is briefly mentioned in which a patient who had re-

these lesions are common. In the malignant phase, neuroretinal edema with a star-shaped figure in the macula flat detachment of the retina and other changes appear. Even here spontaneous remissions can occur. The course of the hypertensive arteri- oclerotic disease complex can be followed reasonably closely with the ophthalmoscope though the correlation is not an absolute one.

Diabetic vascular lesions of the retina. Diabetic retinitis is related much more closely to the duration of the diabetes than to its severity and the regulation of the blood sugar seems to have little effect on its onset and progress. It has been shown that there is an increased capillary fragility in patients with diabetic hemorrhagic retinitis and the author feels there is no doubt that the retinitis of diabetes is a manifestation of general capillary abnormality. He believes that the petechial hemorrhages are formed by small leaks in the capillary endothelium and it has been shown that the endothelium then goes out around the extravasated red cells to form an endothelial sac. Exudates may be caused by smaller leaks allowing only plasma to escape. The course of diabetic retinitis is generally progressive but there may be spontaneous remissions.

ROCKE H. JOHNSON, M.D.

Sugar H. S.: Acute Glaucoma; A Follow Up Study
Am J Ophth. 1947 30 451

In an analysis of 45 patients with a diagnosis of 'primary' acute glaucoma, studied over a period of 6 years it was found that 26.6 per cent showed some significant change during the follow up period. It is believed that clinical descriptions of the vascular reaction in the main diagnosis are not justified.

In this follow up study 3 of the 11 patients with spontaneous attacks of acute glaucoma had no externally visible ocular congestion. It is probable that the classical acute congestive glaucoma, chronic congestive glaucoma, dilatation glaucoma, and 'preglaucoma' are all clinical phases of the same condition.

Acute glaucoma may be superimposed on other forms, such as glaucoma capsulare and simple glaucoma.

Miotics used in treating glaucoma may add a congestive angle-narrowing factor when the angle is already anatomically too narrow. A combination with vasoconstrictors is suggested as a new approach to the therapy of acute glaucoma.

WILLIAM A. MAJOR, M.D.

Thomas, G. J., and McCaullin, M. F.: Pentothal Sodium in Ophthalmic Surgery *Arch. Ophth.* Chlc. 1947 37 451

The authors believe that intravenous anesthesia has a definite place in ophthalmic surgery because the period of induction is short and pleasant, and the depth of narcosis controllable and sufficient. It has the added ophthalmic advantages of a free operative field and of reducing the intraocular tension from 40 to 60 per cent. They believe pentothal sodium has

advantages over the other intravenous anesthetics since it causes less twitching and less postanesthetic nausea and vomiting.

The data is based on over 3 000 administrations of pentothal sodium for all types of ophthalmic surgery in patients varying in age from 7 to 93 years. The satisfactory results are attributed to careful preoperative, operative, and postoperative management. The authors note especially that a barbiturate should be given the night before surgery as a test of the patient's idiosyncrasy to the drug. Administration of atropine is emphasized since it tends to prevent coughing, sneezing or laryngospasm and they believe that cocaine hydrochloride used in the eye tends to prevent sneezing. The oropharyngeal airway is not used for fear of causing laryngospasm, but a tongue suture and a mouth hook are inserted instead. A 4 per cent solution of pentothal sodium is used for patients under 50 years of age and a 2 per cent solution for those of 50 years or older. Nifedipine is given to the older group and to those with coronary disease and arteriosclerosis. During the corneal section and cataract extraction the slow injection of a one half cubic centimeter of pentothal sodium is made with a 20 second pause following each injection. One cubic centimeter of pentothal sodium is given when the cataract is delivered. Occasionally coughing, laryngospasm, hiccup, cyanosis and cardiac embarrassment may occur. Since the most common postanesthetic complication is respiratory depression all patients should be given oxygen continuously until they have completely reacted. Those who fail to react within 2 or 3 hours after surgery have had an overdose of pentothal. In these cases the authors suggest the continuous use of oxygen, frequent aspiration, metrazol, hypertonic solutions of sucrose and repeated small transfusions of plasma. Pentothal sodium is contraindicated when there is interference with respiratory function in bronchiectasis, severe anemia, shock and in children under 8 years of age.

ROCKE H. JOHNSON, M.D.

EAR

Cawthorne Terence: Ménière's Disease *Ann Otol Rhinol* 1947 36 18.

The author discusses clinical details of Ménière's disease on the basis of his personal experiences during the investigation and treatment of more than 400 cases.

He mentions briefly the history of Ménière's original paper and the objections by some writers to the findings in Ménière's typical case. The author states that there is evidence in the literature that the disease has attacked many people who were more or less famous in history and there are even records that it may have affected people in the early days of the Christian era in Rome. More than 50 years ago it was suggested that the cause of the disease was an increase of pressure within the labyrinth and the condition was declared similar to glaucoma. Several other theories concerning the cause of the disease

were mentioned. The author shows several photomicrographs of normal labyrinths and of labyrinths affected by the disease, showing the pathology. Because of the definite pathology it could be stated that a firm basis for the disease was established and that the essential mechanism of the disorder is an obstructive distention of the endolymphatic system. Some men believe that a focus of sepsis may be responsible, although in the author's series of cases under review very few instances of probable foci of sepsis were encountered. The author believes that undue attention has been paid in the past to the influence of eustachian insufficiency and other conditions of the middle ear and even of the external ear upon Ménière's disease. He also does not believe that Dandy's view is correct.

Of the author's 434 cases under review slightly more than half were in males, and three-quarters occurred in patients between the ages of 30 and 60.

The general picture of the disease was highly characteristic and was exhibited by a large proportion of the cases under review although the signs and symptoms varied in their relative intensity and in order of their first appearance. In all cases there were for no apparent reason, periodic bouts of paroxysmal vertigo accompanied as a rule by nausea and vomiting, deafness of the perceptive type, always more noticeable on one side, and tinnitus but no other signs of disease within the central nervous system. A variable, but at times distressing feature of the complaint was the depressing influence of these sudden attacks upon the general well being and every day life of the patient. The nature, intensity, direction and duration of the attacks varied considerably not only from patient to patient but from attack to attack. The bouts tended to occur in groups, there being several within a relatively short period of time followed by long intervals of freedom which might extend over years. In some patients the attacks were always slight, while in others there was a combination of severe and mild attacks. The attacks did not appear to be precipitated by any particular activity but they often occurred in the early morning shortly after the patient arose. Occasionally they awoke a patient from his sleep. In less than half of the cases there was a warning of an impending attack. An increase in the intensity or an alteration in the character of the tinnitus was often noted prior to an attack, while in some cases there was an accentuation of the deafness or an increased dislike of loud sounds. A feeling of fullness, distention, or numbness just behind or in the affected ear was also noticed at times while a headache usually described in terms of pressure or bursting rather than of pain was sometimes experienced. The warning symptoms continued through the attack and at times lasted a short time afterward. In some cases there was a feeling of lightheadedness and slight disturbance of the balance before and after the attacks. The attack usually took the form of the sensation of movement of the surrounding objects less commonly of the subject himself and but rarely a combination of both. The

direction of the apparent movement could very seldom be described by the patient. The attacks might last a matter of minutes or a few hours, and, if severe, would often render the patient helpless. Some patients during an attack would be able to tell themselves home either by walking or occasionally by driving a car. Nausea and vomiting usually accompanied the attacks with varying severity. The vomiting appeared toward the end of the attack and all during the attack. Accompanying the attack were also pallor, cold sweat, a slow thrifty pulse, increased activity of the stomach and biliary passages, and at times even all points of the intestinal tract might be affected as by a strong vaginal spasm, and bowel movements would often make the attack even more distressful to the patient. The two symptoms of a cochlear disturbance, deafness and tinnitus, usually went together and they were rarely absent in the established disease. The deafness was of the perceptive type and presented two distinguishable features. In the first place the deafness was subject to sudden variations and an important feature of this type of deafness was the discomfort due to the distortion of loud sounds, particularly if they were high pitched. Some patients were made more uncomfortable by any sounds, particularly children's voices, the rattle of dishes, noisy planes, and road traffic. Because of this, the hearing on the affected side might be definitely handicapped to a greater extent than by the actual deafness that is present. The hearing commonly fluctuated with the deafness and it was not unusual to find two types of tinnitus in the same ear, such as a constant hum or buzz, and, often before or during an attack, a sound of jangling or chinery. True loss of consciousness during an attack was extremely rare and the author noticed it in only 5 of his cases. Nystagmus of the eyes accompanied severe attacks and often caused a temporary impairment of vision, although no true diplopia or loss of vision occurred without loss of consciousness. Spontaneous nystagmus was seen only during an attack and for a short while after an attack.

The author discusses the diagnosis of the disease and states that it rarely causes any doubt in established cases. The paroxysms of vertigo alternating with intervals of freedom, the perceptive deafness, particularly in one ear, the absence of any signs of disorder within the central nervous system, and the decrease in vestibular function on the involved side are usually characteristic and point toward the diagnosis. The disease must be differentiated from ear tumors, disseminated sclerosis, tumors of the eighth nerve, epilepsy and intracranial vascular disturbances. However the type of vertigo and other signs and symptoms usually help the differentiation.

The treatment of the disease, as also discussed, Once the diagnosis has been made, the first step is to tell the patient what he has, describing to him the pathology behind the disease and the prognosis. When this is done it usually relieves the patient of many worries concerning his condition. He then

know that most of the attacks can usually be controlled and sometimes abolished, although it does not necessarily mean the entire disappearance of all symptoms. In general conservative treatment tends to smother the attacks rather than to abolish them, while surgical intervention although it prevents further attacks may leave some residual dizziness particularly provoked by sudden head movements, and also a tendency to tire easily.

Many different forms of treatment have been advocated. The author refers to an article written previously by himself on this subject. In all of the cases under review he made a trial of conservative therapy. Most of them had had some treatment before particularly with sedatives which was of some help. He found that the exclusion of salt and salty foods from the diet combined with limitation of the fluid intake had resulted in a greater measure of relief than any other form of conservative therapy. The author gives a list of foods that should be avoided. These foods are those which commonly contain a large amount of salt. Added salt for seasoning should be avoided and bread should be baked free of salt when practical. No more than 2½ pints of fluid should be taken in any 24 hours. In addition injections of histamine have been successful in many cases.

Patients whose attacks were not controlled by conservative treatment, in whom only one vestibular labyrinth was affected and in whom the hearing on the same side was obviously impaired were considered suitable cases for destruction of the end-organ. This was usually effected by removing a piece of the membranous external semicircular canal, although it has been found that the same result followed tearing of the canal. Freedom from troublesome complications was attributed to the simplicity of the procedure although in 2 of 135 operative cases mild sepsis supervened. In 5 of 135 operative cases the sacculus endolymphaticus was incised, while labyrinthotomy such as alcohol injection membranous canal diathermy and membranous canal excision was done in 130 cases.

The author briefly describes the operation which is done under general anesthesia through a postauricular mastoid incision and the external semicircular canal exposed by the mastoid route. The incus is often removed to give better exposure. The membranous canal is identified after removal of the bony external semicircular canal. Part of the membranous canal is removed with fine forceps and the mastoid wound is closed without drainage. Of the author's 135 cases 133 healed by first intention and in 3 cases a low-grade infection with ear discharge followed in 2 weeks. There were no other complications and no deaths. As results of his operation in 135 cases the cochlear and vestibular function was abolished in 133 cases and not abolished in 2 cases. One hundred and twenty of the patients were benefited and were able to work, and 9 were not benefited and were unable to work, there is no record of 6 cases. The 2 cases in which both the cochlear and vestibular

function were not lost were cases in which a sacculus endolymphaticus was incised. One difficulty with the operation is that the procedure destroys any hearing in the affected ear but as a rule in the cases coming to operation the hearing is of no value. As a rule the patient's postoperative course is uneventful although there may be some considerable dizziness for a day or so but he is usually out of the hospital in about 3 weeks. He may have some dizziness on quick motion of the head afterward and he may also tire easily. However most patients are very gratified with the results and are glad to return to work within about 2 months after operation.

WILLIAM A. ARTHUR, M.D.

NOSE AND SINUSES

Wright, William K.; Shambaugh, George E., Jr.; and Green, Lois: Congenital Choanal Atresia. A New Surgical Approach. *Ann. Otol. Rhinol.* 1947 56 120

The authors state that atresia of the choana is a rare congenital condition and was first reported in 1839. Two hundred and thirty cases have been reported. The atresia occurs at the junction of the hard and soft palates and extends to the base of the sphenoid bone. About 90 per cent are bony in type and 10 per cent are membranous. A good percentage may be of a mixed type.

There is a low incidence of associated congenital anomalies with congenital choanal atresia. The authors mentioned several existing theories concerning the condition as follows:

- 1 Persistence of the upper part of the buccal membrane.
- 2 Persistence of the nasobuccal membrane.
- 3 Overgrowth of the palatine processes at the choanae so that they fuse not only with the septum but also with the base of the sphenoid bone.

These hypotheses are all difficult to prove or disprove, and the most popular conception seems to be the persistence of the nasobuccal membrane. The flaws in this theory were given.

The authors present a diagram of the embryological development of the choanae.

They report a case of a 23 year old white female who came to the Northwestern Otolaryngological Clinic, Chicago complaining of a mucopurulent discharge from her left nostril of 3 years duration. The patient was unable to blow her left nostril and had never been able to do so. Examination revealed no choana on the left side. A probe passed through the left anterior nares was prevented from passing into the nasopharynx by what appeared to be a bony obstruction in the posterior region. Mercurochrome, and later lipiodol, introduced into the left nostril did not reach the nasopharynx and x-ray films with lipiodol showed the presence of an atresia of the choana which was thicker below than above. The family history and past history were essentially negative. On closer examination it was noted that the lateral

nasal wall on the atretic side protruded medially at its posterior aspect and the floor of this nostril became elevated so that posteriorly it was 1 cm. above the floor of the other side. There was also a lateral deviation of the posterior part of the nasal septum toward the affected side and a medial displacement of the lateral wall of the nasopharynx on the obstructed side so that the left eustachian tube orifice lay almost in the midline. Lipiodol displacement showed absence of the left sphenoid bone with partial pneumatization of the left side by the right sphenoid. The left side of the nose contained typical glairy mucus. Nasal smears revealed many leucocytes but no *cosmophila*.

The authors briefly mentioned several procedures for the relief of this condition such as the use of chisels, gouges, curettes, cautery burrs, and electrocoagulation by either of two routes: splitting the soft and hard palates or by way of the anterior nares. The authors believed that a more adequate exposure than usual had to be done in this case because of the unusual medial displacement of the lateral wall of the nose and nasopharynx, including the sphenopalatine ganglion and the internal maxillary artery with its large branches. It was thought that a better exposure might be made by a Caldwell-Luc incision with removal of the anterior face of the antrum and by making a second window through the medial wall of the antrum at its posterior aspect. The advantage of this procedure would be that it provides a ready access to the sphenopalatine artery via the posterior wall of the antrum in case of unexpected and uncontrollable hemorrhage.

The patient was admitted to the Wesley Memorial Hospital of Chicago and the operation was performed after blocking of the second division of the trigeminal nerve via the posterior palatine canal. No other anesthesia was necessary. The usual Caldwell-Luc procedure was carried out and revealed a normal maxillary sinus. On removal of the lateral wall of the nose into the inferior meatus a thick, hard bony ledge was found projecting medially at a level with the posterior border of the antrum. When the posterior portion of the nasal septum was resected it was found that the thick bony ledge projected medially only slightly more than the lateral wall of the nasopharynx. It was decided that resection of this ledge might open into the sphenopalatine fossa and at best would produce a source of much granulation tissue. Therefore a large rubber tube was inserted through the anterior nares on the left and passed through the perforation in the posterior part of the septum into the nasopharynx. The Caldwell-Luc incision was closed in the usual manner and no other packing or dressing was applied.

The patient's postoperative course was uneventful. The rubber tube was removed after 48 hours and the patient was discharged from the hospital. She was followed up in the clinic and advised to sniff physiological sodium chloride solution into her nose. Epithelialization of the margin of the septal perforation was almost complete in a week and the opening of

the septum remained the same size (about 1.5 cm. 6 months postoperatively to date. The patient was able to breathe through both sides of her nose, although somewhat better on the right which was the normal side. However she could blow either side of her nose equally well and was very well satisfied with the operation. The mucoid discharge from the left side of the nose continued to be greater than from the normal side, but this has caused her little inconvenience as she was able to blow her nose adequately. The secretions however are slowly decreasing and may become unnoticeable in time.

The authors believe that this operation may be of value in other cases of this type in which there is unilateral choanal atresia. There is minimal scapulation and the absence of packs and other foreign material used postoperatively appeared to be responsible for the minimum infection and granulation seen during healing. In many cases described in the literature the postoperative packs, cautery incision of tubes over a long period of time and even epidermal skin grafts on the mucosal surfaces may all have been causing a greater tendency toward scarring and contraction of the new opening. This method gave better exposure to the operative field and better control of hemorrhage with less danger of injury to the pterygopalatine nerves and blood vessels.

WILLIAM A. ARMOUR, M.D.

Dunn, R. E.: Penicillin in the Treatment of Infections in the Nasal Passages and Sinuses. *Aust N Zealand J Surg* 1947 16 185.

The author used four methods in the administration of penicillin for infections of the nasal passages and sinuses.

Local application was adopted in the majority of cases as it offered a high concentration of the drug in the affected sinuses. The Proetz method of displacement was used twice daily supplemented by penicillin drops every 2 hours in concentrations of 250 to 2,500 units per cubic centimeter but 500 units were found to be quite adequate. Blocking of the nostrils by mucosal congestion and by meprobolol during operation prevented effective displacement. Nasal drops of 1 dram of penicillin were inserted in each nostril for 3 minutes every 2 to 4 hours with the patient in the Proetz position. Proof puncture of the antra and instillation of 3 to 4 c.c. of 500 to 5,000 units of penicillin was carried out once or twice a day for a period of from 5 to 10 days. Slow continuous irrigation of the antra with penicillin was carried out for 12 hours and repeated 12 hours later for a similar period.

Prolonged treatment with penicillin encouraged the growth of *Bacillus pyocyaneus*, which was combated by a dilute solution of mercuric iodine without reducing the activity of penicillin. The majority of patients obtained relief from symptoms and, on 12 patients examination showed improvement, although a greater proportion of these would have responded to ordinary conservative treatment, and only a small minority could conscientiously claim that their relief was primarily induced by penicillin. Patients with

secondary infection of the nasal passages following a common cold were benefited. Some patients developed a rash in the vicinity of the nasal vestibule which cleared after the cessation of penicillin.

Intramuscular injection carries the drug to the affected sinuses via the blood stream, but only in limited concentrations; hence one of the disadvantages of this method is that it necessitates large quantities of the drug being used to maintain only a relatively low concentration in the sinus area.

Combined local application of penicillin with oral administration of sulfamerazine was the third method of administration but the advantages of this method are not given.

The fourth method—simultaneous intramuscular injection and local application of penicillin—offered the maximum concentration of the drug in the area of the sinuses. Some patients with penicillin-susceptible organisms were not relieved while some patients with mixed susceptible and nonsusceptible bacterial cultures were relieved.

The treatment of allergic conditions and surgical removal of abnormalities causing stasis in the nasal passages and sinuses are important adjuncts to the penicillin treatment. A. B. VICARIO, M.D.

Robison J. Mathews: Pressure Treatment of Allergic Sinusitis. *Arch. Otolaryng.*, Chic., 1947 45 405.

In support of the therapeutic principles employed the author reviews the pathologic physiology and pathogenesis of allergic sinusitis.

In allergic disease there is an accumulation of fluid in the interstitial tissue spaces of the sinus mucosa. Stagnation of this tissue fluid is part of the pathogenesis of subacute and chronic allergic sinusitis and is responsible for intermittent attacks of infection and progressive degeneration of the mucosa. The factors controlling removal of this fluid from the tissues are arterial capillary filtration, venous capillary absorption, lymph flow and tissue pressure. The factor of tissue pressure is gauged by the resistance tissue offers to dilatation of its interstitial spaces by edema fluid. Acceleration of absorption of this stagnant fluid is accomplished by increasing tissue pressure artificially by means of a balloon filled with iodized oil.

The method consists first of making a small nasotomical opening beneath the inferior turbinate and then after 1 or 2 weeks, the introduction into the sinus of a No. 12 French self-retaining catheter which has had its self retaining head enclosed in a small distensible natural rubber balloon. A few days later the balloon is distended with iodized oil and pressure is maintained by the periodic addition of oil. These balloons may be left in place several weeks or months. By this method patients have been relieved of nasal stenosis due to increased turgescence of the turbinates, recurrence of nasal polyps, excessive secretion of the maxillary sinuses and the bronchopulmonary symptoms of bronchitis, cough and infectious asthma.

Six case histories, accompanied by roentgenograms, are presented. Difficulties encountered during the application of local pressure by the method described may be ascribed to temperament of the patient, the application of excessive pressure, infection and closure of the antrotomy opening, herniation of the balloon into the nose, nasal stenosis due to swelling of the turbinates and fibrosis of the mucosa.

The pressure treatment is most successful in subacute and chronic allergic sinusitis before extensive fibrosis of the mucosa has taken place. The use of the balloon should not be construed as a cure for all types of sinus infection and asthma as it will not return irreversible structural changes to normal. The relief of asthmatic symptoms in some cases indicates that the sinuses may be the source of some noxious substance which is an etiologic factor in asthma. The application of local pressure to the mucosa of the maxillary sinus should be considered as an adjunct to more conservative treatment of allergic sinusitis and not a substitute for any standard practice. JOHN R. LINDSAY, M.D.

Crowe S. J.: Irradiation of the Nasopharynx. *Ann. Otol. Rhinol.* 1946, 55 779.

The author presents as part of a symposium on irradiation therapy in otolaryngology and ophthalmology a summary of his now well recognized views on the effect of irradiation of the nasopharynx. He reviews his early experiences on the effect of irradiation of the nasopharyngeal lymphoid tissue and discusses indications, contraindications, application dosage and results. NOAH D. FARRINGTON, M.D.

MOUTH

May H.: Cleft Lip Repair According to Axhausen's Method. *Plast. Reconstr. Surg.* 1947 3 139.

The author first reviews the methods and procedures which have been proposed and used for closure of congenital cleft lips.

In the discussion he points out the faults of earlier techniques and also the development of better methods which have rewarded the efforts of men who recognized the shortcomings of cleft lip repair.

Credit for the stimulation of the interest in and accomplishment of more acceptable results is given to Veau, Blair and Brown, W. B. Davis, and Ivy and Curtis.

Forceful or early closure of cleft palate is not encouraged, and the author leans toward simple incisions rather than complicated geometric designs. The author believes that no advantage accrues to the concomitant closure of the hard palate and the lip as it increases the operating risk and does not simplify the later palate repair. Axhausen published a monograph in Germany during the war describing a method based on modern principles and aimed at simplifying incisions and utilizing adequate flaps.

As a result of personal experience with Axhausen's method in 36 cases, the author is enthusi-

astatic over his results and offers this article as an evaluation of the method and a recommendation to his confreres for further trial.

The technique for the most common deformity unilateral lip, alveolar process, and palate cleft, is given in detail, with illustrations. The operation is performed between the sixth and eighth weeks after birth if the child is gaining weight and is healthy and after a careful preoperative examination and evaluation of its condition. Axhausen recommends local anesthesia the author however prefers ether vapor. The operation is divided into 4 stages:

1. Formation of the floor of the nostril
2. Correction of the alar displacement
3. Correction of the septum displacement
4. Closure of the lip

The formation of the floor of the nostril is done by utilizing turnover flaps taken from the median and lateral walls of the cleft. (Fig. 1, 2)

The median flap incision extends from the nasal aspect of the columella to the lateroposterior aspect of the alveolar ridge, at the junction of the premaxilla and vomer. Mobilization must be done with extreme care by sharp dissection.

The lateral flap is developed by an incision which starts at the edge of the alveolar process and extends to a point where the alveolar process the tip of the

ala, and the vermillion border meet, and then up into the nostril. This incision must be made with care and precision. The cheek is mobilized from a lateral gingivobuccal sulcus incision. The median and lateral flaps are now sutured with cocaine chromic catgut.

The laterally displaced ala is mobilized, leaving a small flap developed around the tip of the ala. This flap is used to facilitate smooth approximation of the ala to the tuberculum of the columella (Fig. 4). The posterior edge of the flap is sutured to the median and lateral turnover flaps, and the anterior edge is sutured to the outer wound edge of the columella. The median vermillion border flap from the lip is developed at this time (Fig. 5).

Correction of the septum displacement is done by advancement of the mucous membrane along the median gingivobuccal sulcus. Through a sulcus incision the soft tissues are mobilized to expose the septum and the floor of the nose. The tissues are then advanced and sutured.

The formation of the lip is completed by the development of a lateral vermillion border flap of the same length as the median flap. The mucous membrane along the lateral gingivobuccal sulcus as well as the median side and the lateral and median lip sulcus are sutured. Suture is done in three layers: muscle, skin, and mucous membrane (Figs. 9, 10, and 11).

Fig. 10

Fig. 11

Fig. 10. Closure of the lip in layers. The muscle suture is tied posteriorly.

Fig. 11. To counteract notching of the vermilion border at the point of approximation, the vermilion border is

sutured at a different level than the skin. This is accomplished by reducing the vermilion border flap on the lateral side and by making the median vermilion border flap longer.

A nostril retention suture is used and the vermilion border flaps are lapped to prevent notching.

The author follows Axhausen's technique except for minor details. He states that Axhausen's method is based on firm closure of the cleft and correction of the deformities around the cleft, namely deviation of the nose, flattened nostril and shortness of the lip.

The method is said to be applicable to all types of lip clefts and secondary deformities.

FREDERICK W. MERRIFIELD, M.D. D.D.S.

Walker, D. Green: Severe Infections of the Mandible. *Proc. R. Soc. M., Lond.* 1947 40 309.

The author favors the treatment of acute infections of the mandible by systemic administration of penicillin without early surgical interference. Acute infections of the soft tissues around the mandible usually respond well to parenteral penicillin therapy but when abscess formation takes place incision should be made and dependent drainage established.

In local or diffuse chronic osteomyelitis of the mandible, treatment consists of the administration of penicillin and, in addition the timely surgical removal of remaining portions of teeth and sequestra.

Actinomycosis of the jaw responds to penicillin as well as to radiotherapy. Surgery in actinomycosis of the jaw is confined to the incision of abscesses and débridement of the mandible when it is involved. Further work is necessary to establish the optimum dosage for the treatment of infections of the mandible.

JOHN R. LINDSAY, M.D.

Berger: Solitary Central Giant Cell Tumor. *J. Oral Surg.* 1947 5 154.

The solitary giant cell tumor of the jaw bones probably arises in a central nidus. It destroys adjoining tissues and is not encapsulated. It may completely destroy the cortex of the bone and be covered only by mucoperiosteum. Giant cell tumors of the jaw bones are usually less aggressive than giant cell tumors of the long bones. They are not to be confused with surface epuli which are usually associated with some local trauma, are not locally invasive and cause only surface destruction of involved soft tissues and erosion of adjacent bone. It is difficult to differentiate the giant cell tumor from cysts or malignancies by x ray alone. The vacuolated appearance is not a pathognomonic sign.

Six detailed case histories are presented. Five of the lesions occurred in the mandible and 1 lesion occurred in the maxilla. The patients were from 10 to 40 years of age. Four of the 5 patients with mandibular lesions noted anesthesia or paresthesias of the lower lip over the area of distribution of the mental nerve. This symptom is considered to be pathognomonic or strongly suggestive of a neoplasm in differentiation from a cyst. Two patients were treated by surgical removal of the lesion which necessitated the removal of teeth. The defect had filled in with new bone and the patients were clinically well when last seen (5 and 12 years postoperatively). One of these had a history of two previous operations with recurrence. Four patients were given roentgen treatments of these 3 showed healing when last seen (3, 5 and 10 years postoperatively). The fourth patient had been treated too recently to evaluate the condition. X-ray therapy obviates the removal of teeth and bone and consequent mutilation and deformity. A biopsy was made in each case to establish the diagnosis.

JOHN R. LINDSAY, M.D.

PHARYNX

Godfredsen, E.: Malignant Nasopharyngeal Tumors Manifesting Themselves as Parotid Tumors. *Acta. Chir. scand.* 947:95, 1953

The author presents a report of 2 rare cases of malignant nasopharyngeal tumors which manifested themselves as parotid tumors. The condition was not diagnosed correctly at the time because of its polymorphic symptomatology—ophthalmoneurologic and otorhinological with metastatic glands in the neck.

The first case is that of a 36 year old woman who presented an indolent, steadily increasing node of 3 years duration at the angle of the right mandible and covering the lower portion of the right parotid area. Surgical removal revealed the tumor to be intimately adherent to the vessels. It was excised with difficulty. A slight facial paralysis occurred following the operation. Biopsy revealed a malignant endothelioma—a type of mixed salivary tumor. Six months after operation the tumor recurred associated with swelling of the posterior portion of the gingiva of the right lower jaw and shortly ruptured spontaneously. Pus was evacuated. The right facial nerve, masseter and abductor were paralyzed, and there was painful trigeminal neuralgia. A split, nodular fixed mass the size of an apple occupied the right parotid and retroauricular regions. There was no glandular tumor further down the neck. In the nasopharynx a lobate pink submucous tumor arose from the posterior wall and the right superior wall laterally. A roentgenogram of the base of the skull showed a large, osteous destruction on the right side, involving the foramen lacerum, rotundum, and ovale and the fifth and sixth cranial nerves. The microscopic picture was a cytodendrocytic atypical salivary gland tumor from the nasopharynx, with regional metas-

tases to the lymph glands of the right parotid gland. Roentgen therapy for a period of 67 days, during which 7,265 roentgens were administered, cured the primary tumor and the pains subsided but complete freedom from symptoms was not obtained. Ten years later the condition had progressed to a massive intracranial tumor, with right ophthalmoplegia, impaired vision, exophthalmos and choked disc. Death occurred in 4 years and 8 months after the diagnosis had been made.

The second case was that of a 48 year old man who presented a steadily increasing tumor of the right parotid gland, of 3 to 4 months' duration. Excision was made of a grayish soft mass the size of a walnut, which had extended deep into the submandibular fossa. The tumor was diagnosed as a reticulocell sarcoma. Three weeks later recurrence was ascertained. A diffuse firm, elastic, lobulated mass the size of half an orange was found to be deeply adherent to the neck. Rhinoscopically and roentgenologically a nasopharyngeal tumor could not be demonstrated. Following local roentgen treatment of the right parotid area, the tumor disappeared quickly. One year later a tumor appeared at the left parotid gland. It disappeared promptly on irradiation. Another year elapsed before a node was observed in the left supraclavicular region, which also disappeared following roentgen treatment. Rhinoscopy of the nasopharynx was negative, but roentgenograms revealed a swelling of the soft tissue of the roof. Fifteen months later the patient developed a right trigeminal neuralgia and paralysis of the masseter and oculomotor nerves, as well as nasal stenosis and hypoxemia. A flat submucous tumor in the roof and posterior wall of the nasopharynx appeared without swelling of the cervical glands. Unfortunately biopsy was omitted. A roentgenogram of the base of the skull showed no osseous destruction. Roentgen treatment of the nasopharynx for a period of 30 days (7,300 r) left the patient almost symptom-free but death occurred 4 months later (4½ years after the onset of symptoms), due to massive intracranial tumor invasion and distant metastases to the kidneys.

The article contains a brief review of the symptomatology and histopathology of both malignant nasopharyngeal and parotid tumors. In cases of parotid tumor the author emphasizes the importance of considering the possibility of metastases from a primary nasopharyngeal tumor as illustrated in the report of the cases presented.

A. B. PIERCE, M.D.

NECK

Bazzocchi, G.: Retrosternal and Intrathoracic Goiter (Sul gozzo retrosternale ed intratoracico). *Atti chir.* 946:35, 1954

Of 321 thyroids observed over a 15 year period and treated surgically, only 8 were retrosternal or intrathoracic. No case was exclusively endothoracic. The 8 patients were equally divided as to sex.

The subjective symptoms of goiter are as follows: stridor, attacks of nocturnal dyspnea, dysphonia, dysphagia secondary to compression of the esophagus, headache and a sensation of congestion of the head.

Inspection reveals a mass which is continuous from the cervical to the retrosternal region. Either a true edema or a cyanosis of the face especially of the lips, may be seen. Dilatation of the veins of the neck or upper thorax, and palpitation with retardation in the radial pulse may be present. Compression of the sympathetics produces unequal pupils. Percussion may reveal a retrosternal mass. Lesser symptoms such as paralysis of the phrenic nerve, hydrothorax or even chylothorax have been reported in the literature.

X rays reveal the mass or deviation of the trachea laterally and also may show displacement of the esophagus.

Laryngoscopic examination is useful in some cases, but a puncture biopsy rarely may be used for diagnosis.

In the differential diagnosis one must consider mediastinal and bronchopulmonary tumors, aneurysms (aortic, subclavian and innominate) and lastly, adenopathies.

Although substernal thyroids are rarely malignant they should not be treated lightly in older individuals.

Surgery is indicated in any cervical goiter that develops retrosternally although if symptoms are not severe the author advises conservative treatment for in females up to the age of 20 the condition may disappear spontaneously. Local anesthesia is the method of choice in most cases with a block from C₄ to C₆ bilaterally. Care must be taken in ligating the inferior thyroid vessel for it is carried down with the thyroid. The entire mass must be taken out or necrosis may result followed by hemorrhage which may predispose to infection of the mediastinum. A fragment of the capsule should be left in order to avoid opening of the pleura.

Complications which must be watched for are as follows: hemorrhage usually occurring after the sixth hour; paralysis of the vocal cords immediately following surgery (this occurs frequently but the

voice returns), and tetany (rare after 24 or 48 hours) which responds to treatment.

ARTHUR F. CIPOLLA, M.D.

Lundback, Knud: Investigations of Some Biochemical Changes Occurring during the Treatment of Hyperthyroidism. *Acta med. scand.* 1947 127 193

The author carefully studied the biological changes occurring during the treatment of hyperthyroidism with methylthiouracil. In addition 2 cases on iodine therapy were studied and compared. The study of each of these cases extended over periods of from 3 to 6 weeks.

Six cases were studied. One was restudied during thyroidin therapy for the myxedema that had been produced by overdosage of the methylthiouracil.

The conclusions can be summarized as follows:

1. No differences were demonstrable between the effects of methylthiouracil and iodine.

2. The decline in the minimum pulse rate was often completed before the decline in the basal metabolic rate.

3. Gain in body weight began immediately or after a latent period.

4. Serum cholesterol proved an extremely sensitive registrar of thyroid function.

5. Serum urea acid failed to exhibit uniform changes.

6. Frequently there was a brief transient increase in cell volume and serum protein probably reflecting an alteration in hemoconcentration during the fall in the basal metabolic rate.

7. The nitrogen content in the urine showed a tendency to fall during the period of observation.

8. The urinary excretion of creatinine remained within normal limits in all but 1 case.

9. The urinary excretion of calcium exhibited a decrease usually after a latent period of about 1 week.

10. The urinary excretion of sodium and chloride decreased in 1 case during the fall in the basal metabolic rate but remained unchanged in another.

11. No uniform changes were demonstrable in the urinary volume. Three patients exhibited a mild polyuria.

Schatzki, R., Baxter D. H., and Troland G. E.: Second Day Encephalography with Particular Reference to the Size of the Ventricles. *England J M* 947 236 4 9.

The authors report the results of encephalographic studies on 60 patients. Further roentgen study was made the day following the encephalography. The cases included patients who previously had had open head injuries, closed head injuries, convulsive states, and a variety of other conditions.

Measurements were made of the ventricular size on the day of encephalography and similar measurements were taken on the following day without the introduction of more air.

Of the 60 cases in which second-day measurements were made the ventricles were found to be larger on the second day in 23 cases (38%). A slight decrease in the size of the ventricles was found in 3 cases. In 22 cases there was no appreciable change and in 22 cases the amount of air in the ventricles was insufficient to measure. All the cases with pronounced secondary enlargement fell into the group with head injuries.

Porencephalic cysts have been identified in the second-day films when they were not visible in the original studies. In 8 cases a bulging of the inter-ventricular septum was noted on the second day.

The authors discussed the possible theories to account for the alteration in ventricular size. A satisfactory explanation is not available although the authors are inclined to believe that second-day enlargement may represent the true normal or resting size of the ventricle and that the first-day measurements may represent a temporary constriction resulting from the withdrawal of fluids and the sudden introduction of air. They further believe that marked enlargement of the ventricle on the second day is usually seen in association with previously damaged brains. For this reason it is suggested that second-day studies be carried out when one is investigating the possibility of brain injury resulting from a former trauma.

HOWARD A. BROWN, M.D.

Abbott K. H. Penicillin in Treatment of Cranio-cerebral Injuries of War. *Surgery* 947 33.

The author describes his experience with the use of large doses of penicillin in the treatment of cranio-cerebral injuries with particular reference to the local application of penicillin in the ventricles and brain as well as the use of large doses in the subarachnoid system in patients with meningitis.

In a series of more than 200 cases of cranial injury in the southwest Pacific theatre of operations, 63 patients with severe compound cranial cerebral injuries received penicillin in the intracranial wounds. It is

stated that no untoward reaction was observed in this series of cases and dosages on the order of 50,000 units of penicillin were introduced into the ventricles. Penicillin in the amount of 100,000 units was introduced into the cisterna magna in a case of pneumococcal meningitis.

In a footnote attention is called to the more recent reports on the toxic effects of penicillin in the nervous system, which appeared after the present paper was submitted for publication. The author believes that perhaps impurities in penicillin might account for some of the reactions reported by other workers but he discarded this theory in view of the more detailed work by investigators in this country. He concluded that it would seem preferable to continue penicillin therapy with smaller doses, and gradually increase the concentration when it is being used in direct application to the central nervous system.

HOWARD A. BROWN, M.D.

Ecker, Arthur D.: Pedicled Pericranial Grafts for the Repair of Dural Tears in the Temporal Fossa of the Skull. *Arch. Otol. Clin. Res.* 377.

Pointing out the necessity of excluding the contents of the outside world from the intracranial space in the event of severe basilar fractures of the skull and cerebrospinal rhinorrhea, and with the fact that the fluid must be contained within its normal confines, the author presents a method of repair of the dural defect, such as seen over the cribiform plate using a hinged pedicle flap of pericranium.

After a bifrontal scalp flap has been raised and removing the pericranium along with the tissue of the inner layer or pericranium, a strip of the second apron of tissue. A right-angled incision extending across the midline is then cut and bent outward to the right, hinged on to the pericranial muscle. The defect is then explored and any débridement of the brain which is necessary is done. The dura and contents are evacuated from the site of injury. The apron of pericranium is brought backward across the craniotomy and laid upon the midportion of the anterior cranial fossa so as to extend well beyond the dural defect and the dura is then sutured back into place. The weight of the apron will hold the dura in close apposition to the bone lying between it and the bone, so that it is not necessary to hold the graft in place. The apron is then wired into position so that it does not pass the graft which has, at this point, been passed between the edge of the flap and the orbital bone.

Several case histories are reported to show the effectiveness of the operation.

Anderson Frank, M.: Subdural Empyema Secondary to Frontal Sinusitis. Review of Clinical Features and Report of 3 Cases. *Ann. Otol Rhinol.* 1947 56 5

The author believes that subdural empyema is a common intracranial complication of frontal sinusitis, occurring most often over the cerebrum but rarely over the cerebellum; it is frequently overlooked in the clinical diagnosis with death as the result of mistaken or neglected diagnosis. The condition may likewise follow infection within the other paranasal sinuses or the middle ear. The mode of entry of the organisms is usually by way of thrombosed dural veins. The layer of pus, which may be widespread, is actually protected from direct contact with the brain by the arachnoid unless a breakthrough occurs, as may indeed happen. The author states that subdural empyema should be suspected when, in the presence of frontal sinusitis there is "orbital swelling, persistent headache, malaise, fever at times, with chills, meningeal signs and lethargy." The appearance of focal or generalized convulsions, hemiparesis, aphasia, and deviation of the eyes assure the diagnosis and indicate that surgical drainage is imperative.

Subdural empyema may exist together with extradural abscess formation. The differential diagnosis rests between intracerebral abscess, longitudinal sinus thrombosis, or purulent meningitis. The treatment is surgical drainage with supporting chemotherapy.

Three case reports are given in some detail to illustrate the difficulties of diagnosis and results of proper surgical care. JOHN MARTIN, M.D.

Kristoff F. V., and Odom, G. L.: Ruptured Intervertebral Disc in the Cervical Region; A Report of 20 Cases. *Arch. Surg.* 1947 54 187

The authors present 20 cases of ruptured intervertebral disc in the cervical region, 16 of which were cases with uncomplicated nerve root compression and the 4 others were cases of pressure on both the cord and root combined. The authors stressed that the high percentage of cases with root compression alone as compared to those noted in previous reports suggests an earlier recognition of the correct diagnosis. The pathogenesis may be divided into (1) the period of root compression, (2) the period of unilateral cord compression with or without marked root compression and (3) the period of bilateral cord compression with marked unilateral or bilateral root compression.

During the period of uncomplicated compression of the root the subjective complaints are usually pain in the lower neck that soon is followed by pain radiating from the neck down to the shoulder and arm accompanied by paresthesias in the more distal area. Both pain and paresthesias are aggravated by movements of the head and neck which result in direct compression of the nerve root. Objective signs are either those of mechanical defense or neuropathologic signs. The former act to protect against com-

pression of the nerve root. These are tilted head, wry neck, tenderness to manipulation of the lower cervical spinous processes and most reliable of all tenderness to hypertension and lateral flexion of the head toward the side of the pain. These movements tend to reproduce pain and paresthesias. Neuropathologic signs consist of selective hypotonia, weakness, and in late phases, fibrillation and atrophy of certain arm muscles, dissociated sensory impairment in special dermatomes and last, diminution of certain reflexes. The latter are indicative of degeneration of the nerves involved.

Diagnosis of a ruptured disc at the fifth cervical interspace may be made when pain and paresthesias are referred to the radial side of the arm, thumb and index finger. Sensory impairment may or may not occur in the same distribution. Weakness is found in the deltoid and biceps muscles with loss of biceps reflex. A ruptured disc at the sixth cervical interspace can be diagnosed when pain and paresthesias are referred to the extensor side of the arm, dorsum of the hand and one or all of the 3 middle fingers. Sensory impairment occurs in the same area. Weakness appears in the triceps muscle and the triceps reflex is diminished. Listed and described in the differential diagnosis of a ruptured cervical disc with uncomplicated root compression are: cervical arthritis, the scalenus anticus syndrome, laminar cervical fractures, cervical rib, subdeltoid bursitis, brachial neuritis, Pancoast's tumor and cervical radiculitis. The use of oblique x-ray views of the neck and cervical myelography are discussed as part of the diagnostic armamentarium.

If root involvement goes on to unilateral cord compression the root signs will be masked by the cord signs, which are ipsilateral pyramidal tract signs, and contralateral spinothalamic involvement with an indefinite sensory level several segments below the actual lesion. The root signs such as weakness of the muscles, fibrillation, and diminution of the tendon reflexes of the arm will be attributed to a lesion in the anterior horn. No differentiation can now be made between a herniated disc and a spinal cord tumor. It may be that an unrecognized lesion with unilateral cord compression may go to complete bilateral cord compression because of further protrusion of the disc. Root signs may no longer be recognizable. The differential diagnosis may have to include syringomyelia, intramedullary tumor and even occasionally subacute combined degeneration of the spinal cord. However the final diagnosis may not be made until the lesion is exposed. Note was made that manometric studies and total protein estimations did not seem to aid much in evaluating the level of the lesion.

Operation is performed with the patient in a sitting position under tribromoethanol and intratracheal ether. The routine method of exposure is carried out. The herniated disc is removed with forceps and no attempt is made to curet the interspace.

As an addendum the authors mention 18 other patients who had been operated upon; 1 of these had

combined root and cord compression while the others had uncomplicated root compression.

RICHARD C. SCHNEIDER, M.D.

Golnard, P., Descara, P., and Garré, H.: Traumatic Meningitis and Ventriculitis (Ménigites et ventriculites traumatiques) *J. chir. Par.* 1947 63 7

Traumatic meningitis, formerly considered absolutely fatal, is now amenable to cure by chemotherapy. The criterion of cure is a negative cerebrospinal fluid for at least 3 days. Although usually following war wounds or fractures, traumatic meningitis may also follow skull injury without fracture. Besides the usual organisms encountered, the authors found a case due to Pfeiffer's bacillus. In the presence of multiple wounds, care is urged in the evaluation of scalp and spinal wounds. The dangers of incomplete preoperative shaving and of using muscle from suspect areas for hemostasis are stressed also the danger of finger contamination of the wound by disoriented patients. Meningeal infection may also be favored by juxtadural hematomas, serous meningitis, and concomitant shock, as well as an intracranial aspirative vacuum.

Meningitis following basal fracture is rare but usually more serious and may under certain circumstances present a condition similar to perforation peritonitis. Escape of cerebrospinal fluid via the natural cavities may afford temporarily adequate drainage but once blocked there remains only a dangerous port of entry.

Ventriculitis, although rare, may result from direct contamination by a missile from ventricular fistula of surgical origin, or from imperfect closure of the dura mater or hairy scalp. Infection following fistulization increases the cerebrospinal fluid pressure and leads to rupture of sutures; this enlarges the fistula and creates a vicious circle.

Following a discussion of the pathology and clinical picture of the various types of meningitis and ventriculitis, the authors mention newer forms of meningitis caused by bacteriostatic therapy. Among these there is a prolonged but nevertheless fatal type, a type with late onset and prolonged attenuated course, and an aseptic puriform meningitis due to repeated subarachnoid injections of penicillin. In the prolonged fatal meningitis, temporary improvement following treatment is followed by recurrence again and again with progressive deterioration until finally autopsy reveals a diffuse purulent involvement. Repeated inadequate doses of penicillin change the morphology of the organisms, streptococci or staphylococci taking on the appearance of pneumococci.

Inadequate treatment may leave an aseptic puriform meningitis easily cured. In cases of meningeal reaction to penicillin the cerebrospinal fluid is transformed into a thick, whitish purée which will not pass through the puncture needle. It retrogresses only after cessation of the penicillin therapy.

Ventriculitis due to perforation, with ventricular inundation from rupture of a contiguous abscess and

which was formerly fatal within a few hours, responds to prompt incision and evacuation of the ventricle followed by saline irrigation and intraventricular injection of penicillin.

Subacute fatal ventriculitis is a creature of bacteriostatic therapy. Because of the penicillin, the cerebrospinal fluid may remain almost clear after the organism has been demonstrated. Recissions and exacerbations follow to a stage of severe diffuse rigidity and fatal termination. There is a type of regressive suppurative ventriculitis and a condition of one ventricle containing a pusy exudate. The authors noted response of intracranial pressure and confusional symptoms to withdrawal of the residue in 1 case.

Except in delayed meningitis, spinal puncture should be delayed until the fifth day following injury exploration via the trephine being less dangerous. In late meningitis, care is needed to exclude tuberculous meningitis. Ventricular puncture in meningitis of the convexity compensates therapeutically for its potential dangers, if made under the cover of intraventricular injection of penicillin. Ventriculography in abscess is justifiable only when indispensable for localization. After abscess evacuation it should be used if there is any doubt of rupture, asepsis, and it is immediately imperative as the least suspicion of ventricular inundation. Ventriculography is indicated in late ventriculitis in the case of involution and occasionally for ventricular fistula. Harmful though temporary hypertension can be considered. Intraventricular injection of penicillin will break the vicious circle caused by the fistula.

Improvement in statistics are also due in part to advances in neurosurgical technique. Drainage of cranial wounds is now superficial except for the local introduction of penicillin. Imperable also comes with autografts, if necessary is imperative.

Meningitis may develop in spite of preventive chemotherapy. The authors use sulfonamides and penicillin, both systemically and locally for prophylaxis. They make a paste of penicillin solution and sulfonamide. In basal fractures, nasal instillation of penicillin powder has been recommended. For curative treatment sulfonamides and penicillin are given parenterally and penicillin, or if preferable, sulfonamide by the subarachnoid route. Cures have followed the intramuscular administration of penicillin in cases of meningitis developing in spite of sulfonamide therapy. The subarachnoid route was superior. The ventricular route is recommended chiefly for hyperacute cases. The suboccipital route may be cautiously be preferable to the spinal, since repeated punctures are better tolerated. Intrathecal injections combined with systemic administration yields the greatest certainty of cure.

As regards dosage the intramuscular dose is from 100 to 200,000 units daily and the subarachnoid dose not more than from 20,000 to 30,000 units daily in a dose. Larger doses over too long a period may cause aseptic puriform meningitis. To avoid irritation of the subarachnoid space, a solution of

SURGERY OF THE NERVOUS SYSTEM

to 1,000 units of penicillin per cubic centimeter should be diluted with serum to 1,000 units per cubic centimeter especially for cases of ventriculitis. Some cases of meningitis have responded to much smaller doses, but, when possible it is much better to give a large initial dose and repeat it regularly for 6 or 7 days. Subarachnoid injections which are better tolerated. Associated surgery may be required to prevent relapses. Surgery is usually required for a fissure in the basal region connecting a septic cavity with the nasal fossa or petrosa. This must be occluded with a piece of fascia lata.

In ventriculitis due to inundation following rupture of an abscess an emergency operation is indicated. Evacuation of the abscess must be supplemented by ventricular puncture lavage of the ventricle with serum and injection into the cavity of the ventricle with serum and injection into the cavity of the ventricle with serum and injection into the cavity of the ventricle with serum. For the first few days, only the ventricle on the side of the abscess is treated. Then after several days, when the infected ventricle has been rendered aseptic, the treatment is directed to the other ventricle. At the same time penicillin is administered parenterally and same time penicillin is administered parenterally and same time penicillin is administered parenterally. In less than a week the cerebrospinal fluid will be aseptic. The treatment of ventriculitis with ventricular fistula is more tedious, including closure of the fistula with a graft of dura mater and meticulous autoplasty of the hairy scalp. Intensive treatment of the concomitant meningitis is accomplished with subarachnoid injections of penicillin. Stricker reports cure of 1 case by this method.

EDITH SCHANZKE MOORE

SPINAL CORD AND ITS COVERINGS

Inman, Verne T., and Saunders, J. B. deC. M.: Anatomoclinical Aspects of Injuries to the Intervertebral Disc. *J Bone Surg.* 1947 29 461

The authors who are orthopedic surgeons, recognize two factors in the problem of the pathology of the injured intervertebral disc first, that of deranged spinal mechanics and second the effects of spinal nerve irritation and compression. They point out the physiological importance of the high water content of the nucleus pulposus and the tension under which it normally exists. The resiliency of the spine, however, and the motions permitted to it are not due to any elastic turgor of the nucleus, but rather to the elasticity of the ligamentous structures. The deep, aching pain seated within the low back area, at the level of the pathological disc, is due to ligamentous strain and irritation of the ligamentous structures being among the more sensitive tissues of the body. Obviously the segmental pain is due to the pressure of the herniating mass upon the nerve root or roots. A rather novel interpretation of pain of the "fast and slow types is given.

The authors would divide patients with injury of the intervertebral disc into three categories. First patients with deep pain in the back and with pain

extending into one or both lower extremities due to local ligamentous irritation and strain are properly treated by immobilization and support. Second there are patients with local backache due to ligamentous strain and vertebral instability who also have segmental pain due to compression of a root. In this group mere removal of the herniated disc alone will not give the patient complete relief by curing the compression only since unless the painful ligamentous structures are protected the backache will persist. Third there is a minority of all patients who have little or no backache but who present signs of neurological changes of a segmental nature and removal of the herniating mass and decompression of the nerve root will give good relief if surgical intervention is sufficiently prompt. An interesting and lengthy discussion of the paper as read is appended.

JOHN MARTIN M.D.

PERIPHERAL NERVES

Potter, S. E., and Croce, E. J.: The Treatment of Peripheral Nerve Injuries Complicated by Skin and Soft Tissue Defects. *Ann. Surg.* 1947 125 349.

Because the authors believe that at times proper early repair of an injured peripheral nerve may be sacrificed in order to obtain a good cosmetic result in an extensive wound through plastic surgery or vice versa they present the thesis that it is altogether surgically sound and technically possible in many patients to perform the plastic and neurosurgical procedure at the same operation. Some alteration in the incision for the nerve repair may have to be made from the standard approach, but in 7 patients treated by the combined operation, good exposures were obtained, standard methods of nerve repair were carried out, and defects in the soft tissues were closed with good tissue, assured of viability with the use of pedicle grafts.

The authors do not favor the use of free grafts for the closure of defects in a wound containing a sutured nerve, believing that such grafts may (as when used in other types of defects) become ischemic and deter the results of the nerve repair. For the repair of defects of the upper extremity they use the anterior abdominal wall for the source of the pedicle flap for the repair of defects of the lower extremity they use the opposite extremity. The standard methods of plaster fixation while the graft is still on the pedicle, and pressure dressings are used. The donor site is treated by the application of sliding skin grafts. Local anesthesia is used.

JOHN MARTIN M.D.

Davis, L., and Perret, G.: Methods of Nerve Repair *Surg. Clin. N. America* 1947 27 117

It is the belief of the authors that as a general principle, the earlier a nerve can be sutured after injury the better are the chances for effective regeneration of that nerve. They believe that primary suture in a fresh wound should always be done and

that, even in a wound suspected of being contaminated, the nerve should be sutured if such a procedure can be carried out without additional trauma or undue tension at the suture line. They suggest the local and systemic use of antibiotic drugs in such instances.

In cases of large and obviously contaminated wounds in which there is gross destruction of the nerve over a distance it is best to fix the nerve ends by a stay suture in order to prevent retraction and loss of identification in the dense scar that will have to be dissected when the eventual nerve repair is done weeks or months later.

The various methods of nerve repair are mobilization of the nerve, relaxation of the nerve, transposition, primary end-to-end approximation of the nerve fragments, stretching with secondary end-to-end suture, transplantation of nerve grafts, and nerve to nerve anastomosis; all these are to be used alone or in combination, whichever method the case may require.

The authors have had extensive experimental and clinical experience with nerve grafting and while they recognize the superiority of autogenous grafts when grafts are necessary they point out that such grafts are seldom obtainable and that the use of fresh homogenous grafts may serve as second choice, with good results in some cases. Simple end-to-end suture approximation is the method of choice when it can be done.

The technicalities of the usual silk suture technique is discussed, as well as the newer method of plasma clot suture. The use of an impermeable protective layer of any material about the suture line is discouraged by these authors; they point out that the vascularizing effect of the surrounding tissues of the nerve bed is necessary for proper nutrition of the suture line or of the inlaying graft. The senior author's interest in the follow-up care of peripheral

nerve injuries, particularly as it concerns physical therapy is re-emphasized. JOHN MANN, M.D.

SYMPATHETIC NERVES

Threadgill, F. D.: Afferent Conduction in the Sympathetic Ganglia Innervating the Extremities. *Surgery* 1947 21: 569.

The author was induced to reconsider the old and argued subject of afferent conduction within the autonomic nervous system by the fact that under some such conduction pathways the relief of some various disease states by appropriate sympathectomy cannot be explained. In specially prepared animals (the experiments being illustrated by excellent diagrams) he has shown the effect of painful stimuli, such as heat applied to a foot, or arterial injection of lactic acid distal to the point of blockage, or anatomical removal of the sympathetic reticulating that extremity. He concluded that sympathetic afferents from the extremities are similar in function to the viscerosensory fibers in the spinal trunks, and that the relief of pain brought about by sympathectomy in the various painful disease states may be due to the relief of vasospasm or the blockage of afferent impulses from the vessels and placental coenos apparatus of the extremities, or both. He believes that it is possible that afferent impulses arising from the involuntary structures may pass primarily to the corresponding sympathetic ganglia for "integration" with the sympathetic efferents before they enter the spinal cord.

Early in the pain state, sympathectomy will be effective if there is no change in the spinal nerve, but later in the fixed canalopic state, for instance, sympathectomy will be less effective because of permanent changes in the spinal nerve. The nature of these changes is not discussed.

JOHN MANN, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Corey M. E., MacVine, J. S. and Bigby M. A. M.:
The Treatment of Breast Abscesses with Penicillin. *Brit. M. J.*, 1946 2 845

Methods of treating breast abscesses were studied. Alternate patients were treated in the conventional manner and used as controls. No case was accepted for this investigation unless a well defined tender and indurated mass was palpable in the breast tissue. The infecting organism was the *Staphylococcus aureus* in the great majority of the cases. Secondary infection with the *Streptococcus hemolyticus* occurred in 3 of the controls. The other secondary invaders were the *Staphylococcus albus*, *Micrococcus tetragenus*, and *Bacteria coli* and proteus occurring equally in the controls and penicillin group. Suppuration seems to have been prevented by the sulfonamides, but once pus formed in an abscess it continued until healing was well advanced. None of the penicillin treated patients avoided pus formation. Suppuration seemed to be speeded, localized quickly and disappeared quickly. In the control group there were 22 operations performed on 17 of the 18 patients. In the penicillin treated series there were 4 operations. Complications in the same or group consisted of secondary abscesses in the same or opposite breast or in the axillary glands in 6 cases, septic dermatitis in 3 cases, and hepatitis in 1 case. In the penicillin group 2 secondary abscesses developed following local therapy only and a milk sinus persisted in a third case and prolonged the healing time.

The healing time was estimated from the beginning of the treatment until no further dressing or local therapy was required. Comparison showed that in the penicillin treated group the average healing time was one-half of that of the controls, and that in only 1 case of the former group did the healing time exceed the average time of the controls. Breast feeding had to be stopped in the majority of the controls. In the penicillin treated group the mothers continued to nurse their babies on the normal breast throughout the treatment and resumed feedings on the other breast after healing took place. Hospitalization time of the penicillin treated group was also half that of the controls.

Penicillin (15,000 units every 3 hours) was administered by intramuscular injection in the acute inflamed stage and was stopped as soon as pain diminished the flush faded, edema lessened, and fever subsided. As soon as fluctuation could be detected, aspiration of the abscess under local analgesia was done. Penicillin was given intramuscularly prior to this procedure and was injected into the abscess cavity in volume equal to two-thirds of the volume of pus aspirated. If doubt existed as to the complete localization and it was possible to inject a full 24

hour dose without leakage, 120,000 units of penicillin in the appropriate volume were injected otherwise a solution containing 500 units per cubic centimeter was used. If no sinus formed this procedure was carried out every day until the appearance of sero-sanguineous exudate free of the *Staphylococcus aureus* on smear and culture, at which time treatment was stopped.

Instillations of penicillin were often made through a sinus that formed where the abscess pointed. Pus was expressed from the cavity and the penicillin was instilled by means of a fine rubber tube or needle. The opening was closed by a cotton-iodine dress. The opening in the penicillin. Large cavities containing to seal in the penicillin. Large cavities containing from 100 to 150 c.c. were incised and evacuated. The closure being made around a 5 mm. tube. The tube was used for aspiration of the pus and the instillation of the penicillin. Large cavities were treated twice daily.

Two great advantages of local therapy are the feasibility of introducing relatively large concentrations of penicillin at the focus of the infection and the insurance of drainage and irrigation of damaged surfaces with a minimum of trauma and an increase in the rate of healing.

EDWARD W. PASSARELLI, M.D.

TRACHEA, LUNGS, AND PLEURA

Waldapfel, Richard: Classic and Other Types of Tracheotomy. *Arch. Otol.* Chlc., 1947 45 446

The author discusses the various types of tracheotomy the postoperative care of the patient, and the complications which may arise. Two types of the operation, namely, the emergency and the regular tracheotomy, are described in some detail. The latter is illustrated step by step. The 2 fundamental principles for successful tracheotomy are (1) the cricoid cartilage should never be injured (the trachea is opened a way from the cricoid cartilage, at least as far as the second ring) and (2) provision for the cannula should be made by excision without distorting the tracheal rings. The author employs a specially designed instrument for this purpose. The cannula is held in place by a tape which is threaded through the 2 eyes of the shield of the cannula and tied at the back of the neck of the patient. In the United States the Jackson type of cannula is employed. The most frequently encountered complications are hemorrhage, emphysema, and disturbances in swallowing.

The cannula is removed as soon as the patient is able to breathe both day and night, with the cannula blocked.

Patients requiring permanent use of the cannula as in chronic stenosis, should be taught how to change the cannula before they are discharged from the hospital.

ROBERT TURNELL, M.D.

INTERNATIONAL ABSTRACTS OF SURGERY

Moerach, H. J., and Gaget, O. T.: Pulmonary Cysts. *J Thorac S* 1947 16 179.

Pulmonary cysts are of special interest because of the variability in the clinical symptoms that they may produce and the difficulty that may be experienced in their differential diagnosis. They may be divided into two main types, those arising from the bronchial mucosa and those that are alveolar in origin. There may be various gradations between these two types. The causation of pulmonary cysts is not definitely established. While many cysts are congenital, clinical evidence would seem to indicate that many are acquired. A study of cystic bronchiectasis illustrates the rapidity with which cystic dilatation of the bronchi can take place.

Pulmonary cysts with a bronchial communication are more likely to give rise to clinical symptoms than those in which such a communication does not exist although the latter may give rise to clinical symptoms primarily because of pressure on the neighboring bronchi and subsequent bronchial infection. Cough, expectoration, hemoptysis, thoracic pain, and attacks of fever are the chief symptoms found associated with pulmonary cysts.

Two cases that would indicate that carcinoma may develop within a pulmonary cyst are presented. The best treatment of pulmonary cyst is surgical removal.

Fried B M: Bronchiogenic Adenomas; Benign Tumor of the Bronchus. *Arch Int M* 1947 79 20

Adenomas constitute from 6 to 12 per cent of all bronchial tumors and are the most common benign bronchial neoplasms. They tend to affect the larger bronchi (accessible to the bronchoscope) are more common in the lower than upper lobes are more common in the right lung (58.5%) than in the left and are found more frequently in women (55.7%) than in men. The maximum incidence occurs in the decade from 30 to 40. The author considers bronchial adenomas to be benign tumors, although they metastasize extremely rarely and then after many years.

Adenomas arise either from (1) the bronchial mucous glands or (2) the basal cells of the bronchial mucosa membrane. While characteristically encapsulated, they frequently grow both toward the bronchial lumen and through the bronchial wall toward the lung to produce an "iceberg" or collar button contour a point of importance in the attempt at bronchoscopic removal. When they are confined to the lumen, radium, forceps or electrocoagulation alone may effect a cure. Lobectomy or pneumonectomy is necessary for larger tumors or when there is putrid infection secondary to bronchial obstruction. Early complaints with adenoma are (1) cough productive of mucoid sputum occasionally tinged with blood, (2) respiratory wheeze and (3) abrupt and abundant hemorrhage. Carcinoma while producing hemorrhage rarely causes the profuse hemorrhage of adenoma.

Six cases are reported illustrating various policies arising with bronchial adenoma. In 1 (one) with a lined capsule was believed to have totally excised the blood supply with resultant loss of viability of all the tumor cells—an unusual and curious result. FRANK B (CHIC, N.Y.)

Sano, M. E., and Almeida, R., Jr.: Five Types of Called Adenomas; A Histopathologic Study. *Arch Pathol Chlc*, 1947 43 135

Five cases of bronchial adenoma are reported by the authors with pathologic descriptions. Case 1 illustrates the inadequacy of the local removal of pedunculated bronchial adenoma. This case is shown the intimate relationship of the bronchi.

The presence of bone in the serous glands, however, it is considered insufficient evidence to support the hypothesis that such tumors originate from the developed bronchial buds.

All these tumors are considered to be "mixed" the two component cells being of epithelial origin. The tumors described were found to have weak tendencies and were considered potentially malignant. In 1 cancerous alteration had occurred only for this reason, radical surgical removal is indicated when feasible.

Oncocytes were found in 3 of these cases, but none were they found so profusely as in the case of bronchiectasis, in which no adenoma is located. These cells do not resemble tumor cells.

Jones J G.: Bronchiogenic Carcinoma. *J A M A* 1947 134 3

Bronchiogenic carcinoma accounts for 10 per cent of all cancer in men and about 2.5 per cent of all cancer in women. Reliable statistics indicate that the disease is increasing. Symptoms are nonspecific and degree of obstruction of the bronchi. Cough is the earliest symptom (80%) and discomfort or pain the second most common. Hemoptysis occurs in about one-half of the patients. Roentgenography is the greatest single aid in diagnosis. Bronchoscopy is next most important and will permit biopsy in from 60 to 75 per cent of the cases. The important aid in cases which cannot be biopsied. Needle biopsy is disapproved because of the danger of hemorrhage, infection, and tumor extension along the needle track.

Exploratory thoracotomy with a view of proceeding with pneumonectomy in cases not proved by biopsy is considered entirely safe. The incidence of recurrence following lobectomy makes total pneumonectomy with resection of the regional mediastinal choice. Irradiation only palliates. Preparation for pneumonectomy is essentially the same as that required for other major surgical procedures.

Among 196 carcinomas of the lung seen over the past 4 year period, only 39 per cent (78) were clinically operable. Only 39 per cent of the 66 patients who accepted operation were found to have resectable tumors on exploration (50% of the 196). The operative mortality was less than 4 per cent. Eleven, or 39.5 per cent of the 37 patients who were operated upon and left the hospital are dead of various causes including recurrence and metastases. Survival statistics cannot yet be evaluated for this group.

FRANK B. QUEEN, M.D.

Dorner, B. A. and Wiles, J.: The Intrabronchial Administration of Penicillin and Sulfonamide. *Clin. Proc. Cape Town*, 1947 6: 10.

There are three general indications for intrabronchial therapy of bronchiectasis:

- 1 Cases with a minor degree of bronchial dilatation and symptoms not severe enough to warrant lobectomy
- 2 Cases in which the extent of the disease or the general condition contraindicate lobectomy or those in which the patient refuses operation
- 3 Cases in which it is desirable to sterilize the bronchi and improve the general health in preparation for lobectomy

The difficulty of assessing the results of conservative treatment of bronchiectasis is that the signs of improvement are chiefly subjective. Of a series of 18 patients treated with a sulfonamide-penicillin suspension 14 had sufficient symptomatic relief to make a marked difference in their comfort and well being. The other 4 had from slight to moderate symptomatic relief. In no case has there been permanent relief of symptoms.

In suppurative pneumonitis and lung abscess intrabronchial therapy with a suspension of penicillin and sulfonamide in iodized oil has cured a significant proportion of cases. It is of special value in cases unsuitable for surgical interference.

SAMUEL KAHN, M.D.

Samson, P. C. and Burford, T. H.: Total Pulmonary Decortication: Its Evolution and Present Concepts of Indications and Operative Technique. *J. Thorac. Surg.*, 1947 16: 127

Early investigators recognized that the lung beneath the thickened membrane in chronic empyema frequently was normal and that expansion was prevented not so often by pulmonary disease as by the false membrane deposited on its surface. That the membrane removed by decortication was not thickened pleura but rather a tough fibrotic sheet which was firmly adherent to a relatively normal visceral pleura was recognized early by some workers but unfortunately the erroneous conception that it was "thickened pleura" has persisted almost to the present. The basic essentials of the operative technique described by Delorme near the turn of the century are embodied in present day techniques. Various procedures were described in association with decortication such as thoracoplasty pedicled muscle

transplantation and collapsing parietal procedures of various types, which indicated that at an earlier day the results of decortication procedures were not uniformly successful.

As the result of wide experience with hemothorax and its complications of organization and infection the indications for decortication have been broadened and the operative technique modified. Approximately 10 per cent of battle incurred traumatic hemothorax showed evidence of extensive clotting, and in nearly all of these cases there was some degree of organization. Clinical infection developed in a much larger proportion of clotted than in nonclotted hemothoraces.

The pathogenesis of hemo-organization begins with the laying down of a thin film of fibrin and blood cells over both pleural surfaces into which an angio-blastic and fibroblastic proliferation extends from the pleurae. The hemothorax thus becomes a closed hematoma of the pleural space, the wall of the envelope being composed of an ever thickening layer of fibroblastic and later fibrous tissue. The pleura itself does not become thickened but remains as a thin translucent grossly normal membrane (Fig. 1). Along the inner or younger surface of the membrane active fibroplasia continues and results in progressive thickening. When fully developed the membrane forms a tough inelastic membrane 1 or 2 cm in thickness and that portion of the envelope which invests the visceral pleura effectively prevents pulmonary re-expansion. In many cases, as weeks pass, the fibrosis increases and tufts of scar tissue extend through the pleura into the interstitial tissue of the lung. Hence a degree of cellular intimacy develops between the pleura and membrane so that it may be difficult or impossible to establish a cleavage plane and the invaded lung is only poorly expansile. Calcium may be deposited in the membrane within 3 or 4 weeks.

The success of early decortication depends upon these facts. The occurrence of infection in a hemothorax does not change the essential pathology of hemo-organization although a firmer thicker membrane develops more rapidly in cases in which infection supervenes. Hence in early empyema decortication performed as early as 11 or 12 days after injury has produced mature membranes. It is best to operate in from 3 to 5 weeks after injury in uninfected cases for if operation is done earlier the membrane is thin and friable and the operation becomes extremely tedious, while if it is done too late the fibrous union between the membrane and pleura prevents a clean separation and the lung is frequently torn.

The technique at operation does not differ appreciably whether or not infection is present in the hemothorax. Endotracheal anesthesia should be employed in all cases. The authors prefer an intercostal incision without section or resection of the ribs. The sixth intercostal space is usually the site of election for incision, but the fifth or seventh can be used according to whether better exposure is desired at the

Fig. 1 (Samson, Burford) Schematic diagram showing relationship of an organizing hemothorax (closed intrapleural hematoma) to the collapsed right lung.

apex or at the base. The lung must be freed widely from the region of the incision otherwise extensive tearing will occur when the ribs are separated. All loculi are broken down and if no fistulas are present the cavity is cleansed with saline solution. A sharp incision is made through the fibroblastic membrane (peel) to the visceral pleura. If the lung is braced with moderate positive pressure this maneuver is facilitated. When the visceral pleura is reached the underlying lung will herniate through the incised membrane. During separation the main pressure is directed toward the membrane with either small gauze dissectors or the fingers (Fig. 6). Decortication is carried to the edge of the collapsed lung where the membrane reflects on to the parietal pleura. The fissures and apex are then freed and the lung is separated from the diaphragm, mediastinum and pericardium down to the hilum and pulmonary ligament. This is a most important part of the procedure. No attempt is made to remove the membrane from the parietal pleura for such a procedure has no effect on pulmonary re-expansion and the oozing of the blood is extensive and difficult to control. The diaphragm need not necessarily be decorticated but the cardiophrenic and costophrenic sulci should be re-established to increase diaphragmatic motion and aid in pulmonary re-expansion.

After the lung has been freed attention is given to necessary pulmonary surgery. Tears in the visceral pleura are repaired with interrupted fine silk sutures. Single superficial fistulas may be closed after freshening of the edges. Following decortication, intrapleural foreign bodies are readily palpable, although difficult to locate beneath the membrane in a compressed lung. Infected hematomas and abscesses usually are opened, the necrotic lining is re-

moved by dissection, and the dead space is eliminated by layered closure with fine silk. Wedge resections of these areas or total lobectomy may be necessary. In so far as possible, long sinus tracts in the lung must be laid open, the lining membrane cauterized, and the lung closed in layers. Mere closure of the superficial opening of the sinus tract will not suffice. Rib splinters or metallic fragments protruding into the pleural cavity are removed and a smooth surface is achieved.

Two and sometimes 3 intercostal watertight drains are inserted to maintain pulmonary expansion. Talcine injection of the 2 or 3 nerves above and below the incision is done. A layered closure is accomplished. Blood in amounts of from 1,000 to 2,000 c.c. is always given during the operation.

The postoperative care differs little from that in any major thoracic case. Deep breathing, forced expiration, and voluntary cough are mandatory. Irrigations or instillations are done. Systemic penicillin is given as long as necessary. It is of utmost importance that the intercostal tubes remain drainage. If a fistula develops one tube must be kept in place as long as the air leak continues. If a large empyema develops, as shown by a change to a parent drainage, dependent rib resection drainage should be established at once. A large airtight tube is inserted and attached to a water seal bottle to prevent secondary collapse of the lung.

Patients with an uninfected organizing hemothorax are observed and treated conservatively for from 4 to 6 weeks. Many of the conditions clear and become asymptomatic by the fifth or sixth week. Repeated aspirations are made and the removal of as little as from 50 to 100 c.c. of curd-like material from time to time is advantageous. If the situation becomes stationary at the end of 5 or 6 weeks, decortication is indicated if the patient presents all or part of the following picture: roentgenographic evidence of a generalized hazy chest, bilateral pulmonary compression of 50 per cent or more with a collapsed apex, poor thoracic expansion with retraction and narrowing of the intercostal spaces, diffuse thoracic pain or discomfort, and dyspnea on exertion.

The combination of foreign body retained in a well expanded upper lobe in association with a lower lobe still partially compressed by an organizing hemothorax is considered sufficient indication for decortication and removal of the mass.

In cases of infected organizing hemothorax in which the lung is compressed more than 25 per cent and particularly if the apex is collapsed, decortication should be done as soon as the patient's condition will permit. The difference between infected hemothorax and frank empyema is not great. In the latter instance the infection has been present for a longer period of time or may be more virulent. The author prefers to subject suitable cases to primary decortication without preliminary drainage since penicillin has come into general use. If the patient is profoundly toxic, preliminary rib resection drainage can

SURGERY OF THE THORAX

be done followed by decortication when the patient's condition permits.

Significant decortications were carried out on 125 patients 75 of whom had primary healing and complete pulmonary restoration without the development of recurrent empyema. Most residual empyemas were small and basal in location and responded well to rib resection drainage. When the lung was normal at the time of decortication primary cure was obtained in more than 90 per cent of the cases while in a group with associated pulmonary pathology about 40 per cent presented recurrent empyema. The operative mortality for approximately 1,500 operations is probably less than 2 per cent.

In the early phase, at least, of postpneumonic empyema the pleura is essentially normal. This fact suggests the use of early decortication in selected cases of subacute or impending chronic postpneumonic empysema. The indications should be those of a total or subtotal empyema with a collapsed apex or loculations of the exudate. No conclusions can be made concerning the use of decortication in cases of tuberculous empyema without parenchymal infection.

The above findings are suggestive or diagnostic of a tumor of the heart.

1. Unexplained and intractable cardiac failure which is often the first and the last
2. Unexplained and sometimes inconstant changes in cardiac rhythm sounds and size as judged by physical roentgen and electrocardiographic examinations.

Fig. 1 (Woll and Vickery) through the opened left atrium showing character of the growth.

Tumor seen from above. Note the strikingly oc-

Fig. 2 Microscopic view of the primary tumor. Note the lobulation, the whorled character of the fascicles, the abundance of collagen, and the wide variation of cell size and shape. (Eosin-methylene blue X93)

valvular disease Roentgen studies usually demonstrate the pleuropenocardial pericardiocostal or pericardiophrenic symphyses. Ordinarily the heart is small. Calcific plaques if accompanied by the classical clinical syndrome represent an absolute diagnostic sign. However this sign is frequently lacking as calcification is not always associated with chronic constrictive pericarditis.

The classical forms end fatally within a few years. Ordinarily the duration of life is between 4 and 6 years, during which time the symptoms become progressively worse. Frequently an infection or a pneumonic process hastens the end.

The adolescent form of disease is most amenable to surgery and the best results are obtained in these cases. The children present a fairly typical appearance with small limbs, long narrow faces, smooth white glabrous skin and infantile genital organs. Secondary sex characteristics are lacking. Menstruation either does not appear or is scanty and irregular. The surgical liberation of the heart gives most spectacular results for the growth and development of the child is quite rapid thereafter. The results of surgery upon the adult form are much less impressive.

The operative indications are quite precise if the acute fulminating and the slowly progressing well tolerated forms are excluded. However it is necessary to select an optimum time in the stage of the disease for operation. This problem involves the question of the role of tuberculosis in the genesis of the disease. Tuberculosis is undoubtedly a frequently encountered etiologic agent. Fluid obtained from acute pericardial effusions may show tubercle bacilli either by smear or by guinea pig inoculation. More often the typical tubercles giant cells, and organisms are found by histologic examination of tissue removed at operation or recovered at autopsy. Sometimes a postoperative military dissemination of the disease occurs and gives an exact clue to the bacillary nature of the process. Occasionally one can demonstrate other foci of infection antedating the pericardial involvement. However in 65 per cent of the author's cases careful observation at operation or at autopsy did not demonstrate such a tuberculous etiology. Nevertheless, when no precise etiologic agent can be demonstrated the authors believe that, in most instances, the cause is tuberculous, because tuberculous anatomically forms fibrous constrictions and calcifications. Other entities such as trauma, syphilis, or benign suppuration are without doubt causes of chronic constrictive pericarditis. Certainly the rheumatic etiology is uncommon for the adhesions are usually soft, loosely attached and nonconstrictive.

The tuberculous etiology then presupposes the elapse of a long period before surgery is considered for it is of paramount importance to operate only when the infection is overcome and the lesions are uninhabited by organisms. One risks nothing by the long delay for the myocardial damage is practically never irreversible one risks everything by operating too early. However there are no definite criteria to

determine if the lesion is quiescent and free of organisms. Certainly the existence of other visceral tuberculous lesions, the presence of pericardial fluid and the persistence of temperature with or without adenopathy are absolute contraindications to surgery. No particular sign indicates how long to delay operation. Usually however when the disease has advanced but little at least 18 to 24 months should elapse before operative intervention is attempted. The cytologic picture of pleural and pericardial fluids may aid somewhat for if no inflammatory cells are seen the fluid may be considered a mere transudate.

Local anesthesia is employed almost exclusively by the authors. In contrast to most American surgeons who favor extensive pericardectomies by carrying the excision of the fibrous tissue to the point of origin of the great vessels, these French surgeons believe that a limited pericardectomy which removes only that portion overlying the anterior aspect of the left ventricle is sufficient. The limited excision is easier less shocking and apparently sufficient for the distal repose of the left ventricle is the most important feature. The aorta at the level of the great vessels at the base of the heart is secondary to poor filling of the ventricle.

The authors emphasize that the pleura should not be injured. The use of gentle technique in resection of the ribs and left border of the sternum, with a midline approach to the pericardium and the use of moist sponges to reflect the pleura, aids in preventing its injury.

The authors' experience is derived from the study of 12 personal cases. In 6 of these perfect results were obtained. The results were less impressive in 2 adults of middle age with calcified pericardial lesions and in the 4 other cases in which recurrent pleural presumably tuberculous, infections occurred.

CEVILLE F. GRIMES, M.D.

ESOPHAGUS AND MEDIASTINUM

Thomas, M. A.: Webs and Constricting Bands in the Upper Esophagus (Sideropenic Dysphagia). *Am. J. Surg.* 1947 57 223.

The lesions which the author describes are either thin membranous webs which sweep partially across the lumen of the esophagus or narrow bands which encircle the esophagus and constrict the lumen. The condition is found, with few exceptions, in women and is often associated with essential hypochromic anemia. The postcricoid area is the most common site. The precise etiology has not been established. It is believed that they may be congenital or due to scar tissue forming after some abrasion of the mucosa either as the result of trauma or infection. However more complex etiologic factors seem to be involved. The association of anemia and dysphagia occurs most often. Superficial glossitis, cracking of the corners of the mouth, splenomegaly and achlorhydria may accompany the two predominant symptoms. A disturbance of the balance between the Mefasner

which no amount of medical therapy can benefit. Thirty patients had undergone one or more surgical operations previously for complications of peptic ulcer.

Usually the indications for resection were multiple, but in 39 cases the primary indication was pain in 20 cases obstruction. In 19 cases, bleeding in 7 cases, gastric ulcer without healing in 7 cases, wrong diagnosis in 1 case, perforation and in 1 case, gastrojejunocolic fistula. Gastric resection was not considered for the ulcer patient who was able to carry on full time work and whose condition could be well controlled with medical therapy.

At operation 70 duodenal ulcers, 21 gastric ulcers, 5 marginal ulcers and 1 gastrojejunocolic fistula were found. Ten patients had multiple ulcers. A walled off perforated ulcer was present in 59 per cent of the patients.

Preoperative and postoperative gastric acidity were studied and the average preoperative value was shown to be 50 U at 60 minutes. After surgery the average value was 5. In attempting to correlate the amount of stomach resected with the reduction of free hydrochloric acid a greater percentage of patients with achlorhydria was found among those with a two-thirds resection than among those with a three-fourths resection. The authors offer the explanation that the shorter afferent loop in the two-thirds resections may account for the above finding.

All gastrojejunal anastomoses were of the terminolateral orals totals type 99 were retrocolic. An associated enteroenterostomy was performed in 5 cases, 3 of which were of the en y type after partial jejunal resection for marginal ulcer. Pyloric exclusion was performed in 4 cases only, which reflects the authors opinion that the so called unremovable duodenal ulcers are not common.

Thirty-one per cent of the patients had postoperative complications. In 9 cases there was pulmonary infection, in 5 cases wound infection, and in 3 delayed function of the anastomosis. Obstructed anastomosis incomplete intestinal obstruction laryngeal edema pancreatic fistula, jaundice, wound separation evacuation, intra-abdominal abscess, ascites, and bleeding from the gastrointestinal tract were other complications.

There were 8 deaths. Of these, 5 occurred among patients in whom less than two-thirds of the stomach had been removed. It would appear that the magnitude of the resection per se does not increase the mortality rate. Two patients died because of cardiac failure and 6 died of peritonitis due to a breakdown of suture lines damage to the bile ducts, and wound infection. Case reports are presented of the 8 cases in which death occurred. From these the authors conclude that

1. A patient who has lost large amounts of blood over a period of time is a poor operative risk even though supported by many transfusions earlier operative intervention before succeeding exsanguinating hemorrhages will give a lower operative mortality

2. Gastric resection may be indicated even though the patient has severe heart disease if symptoms are severe enough.

3. Improvements in technique of pyloric stump closure may obviate the difficulty in obtaining a secure closure of the antral mucosa.

4. Poor healing is definitely related to a great blood loss and is responsible for separation of suture lines and fatal peritonitis.

Ninety two patients were available for follow-up studies. Of these 52 were examined later at the hospital and 7 were followed by letters. Using rather strict criteria, the authors found that 51 of the 59 patients were well, 4 were improved, and 4 had a recurrence. There was no evidence of recurrence in the 33 patients who were followed indirectly.

Studies of the 4 recurrent cases showed the presence of high gastric acidity. The authors believe a relative achlorhydria is necessary to prevent recurrent ulcer. It was believed that removal of an inadequate amount of the stomach was the cause of recurrence in 2 cases. In the remaining 2 cases, marginal ulcers were resected with re-establishment of continuity by the en y type of jejunostomy and recurrence was blamed on this type of anastomosis. Secretin is not produced because it is impossible for acid gastric juice to reach the duodenal mucosa. The buffering effect of bile and pancreatic juice is lost since these juices bypass the gastrojejunal anastomosis, leaving it exposed to the acid peptic digestive juice.

The authors report a direct relationship between recurrent ulcer and conservative surgery.

In the 30 patients in whom less than a two-thirds resection was done the recurrence rate was 13.3 per cent, while in the 80 patients with a two-thirds or more resection, the rate was 2.5 per cent. In 21 patients with ulcer which was treated by gastroenterostomy during the same period, the recurrence rate was 27.3 per cent.

Case reports of the 4 patients with recurrent ulcers are given in detail.

During 1944 and 1945 121 additional gastric resections were performed for ulcer and its complications. Forty-one patients had had previous surgery for peptic ulcer. In 31 cases the indication for resection was a severe complication of peptic ulcer or of previously inadequate surgical treatment. There were 4 deaths, a 1.6 per cent mortality. The authors attribute the decreased mortality to refinements in operative technique and careful attention to pre- and postoperative care. Two-thirds of the stomach was removed in a greater number of the patients in this group than in the previous group of 100. Follow up examinations in 92 per cent of this group, although short, have failed to reveal any recurrent ulcers. During this same period only 4 gastroenterostomies for ulcer were performed.

During the 5 year period from 1941 to 1945 the authors report a mortality rate of 4.5 per cent the ulcer recurrence rate was 1.8 per cent.

ROBERT R. BRIDGEMAN M.D.

Barrett M. K.: *Avenues of Approach to the Gastric Cancer Problem. J. Nat. Cancer Inst., 1946 7 127*

The greater number of deaths from cancer are among patients with gastric cancer (26,000 to 40,000 yearly). Since the problem is of major importance, the author has made a study of over a thousand articles and books in an effort to find suggestions for further clinical or experimental work. Factual knowledge of the major associations and relationships of gastric carcinoma are summarized in twelve sections as follows: Heredity, Diet and Vitamins, Hormones, Bacteriology, Gastritis, Pernicious Anemia, Achlorhydria, Ulcer, Gastric Polyps, Methods of Diagnosis, and Experimental Carcinogenesis. General suggestions are made for further study along various lines.

The most pressing need is for earlier diagnosis. With the best treatment, the average percentage of 5 year survivors is but 5 or 6 per cent. The author states that only one-half of all patients hospitalized or gastric cancer are operable, and of these, only one half of the cancers are resectable.

Methods feasible for attaining early diagnosis in a large number of cases are not now apparent.

FRANK B. QUEEN, M.D.

Wahren H.: Total Resection of the Carcinomatous Stomach. *Acta. chir. scand.* 1947 95 193

Total gastrectomy in cases of carcinoma of the fundus and upper corpus of the stomach is advocated by the author not only because subtotal resection *a priori* fails to fulfill the theoretical demands for radical treatment of a cancerous process but also because of the observations of Borrmann and of Eker who showed that cancer cells could be demonstrated in tissue as far as 5 cm. from the palpable tumor but appeared to be healthy macroscopically. According to various authors lymphatic metastases occur in from 36 to 75 per cent of the cases of ventriculoesophageal carcinoma.

Pentontitis originating in the anastomosis between the esophagus and the jejunum and/or the duodenum is probably the most usual cause of death following total gastrectomy. For this reason the author carefully preserves the ascending branch of the left gastric artery upon which the lower portion of the esophagus is dependent for its nutrition to a high degree, although such a maneuver lessens the possibility of effectively removing the lymphatics in the region of the cardia.

A technique of total gastrectomy and esophagojejunostomy through a subcostal, upper left abdominal incision is described. Section of both vagi and incision of the peritoneum anteriorly and posteriorly over the abdominal esophagus allows the surgeon to elongate the subdiaphragmatic portion of the esophagus some 5 to 7 cm. without too much traction. The esophageal stump is closed with steel wire and folded upward so that an anastomosis to the jejunum may be effected on its posterior surface. The author believes that extirpation of the spleen along with ventriculectomy as recommended by some

American surgeons, is irrational. Protein derivatives are given intravenously during the immediate postoperative phase.

Nine cases of total gastrectomy for carcinoma of the corpus are reviewed, all of the patients were discharged from the hospital in good condition. One patient was living 10 months after the operation, but showed evidence of metastasis to the liver. Three patients died in from 4 to 14 months of liver metastasis, and 1 other patient died after 4.5 months, but the cause of his death was not determined. The 4 remaining patients are living from 1 to 2 years postoperatively and are apparently well.

WAYNE CAMERON, M.D.

Puente Duany N. and Elizondo Martel G. Radiologic Aspects of Gastrointestinal Lymphosarcoma—Lymphoblastoma (Aspecto radiológico del linfocarcinoma—linfoblastoma—gastrointestinal). *Arch. cubanas cancerol.*, 1946, 5 361

Puente Duany and Elizondo Martel have made a very comprehensive clinical and radiological study of 23 cases of lymphosarcoma of the gastrointestinal tract. Twelve of the lesions were located in the intestine, 10 in the stomach, and 1 affected both segments. The article is illustrated by a large number of x ray reproductions and drawings of the different lesions found. Lymphosarcoma was found more frequently in the intestine, especially in the ileocecal valve, than in the stomach. With exception of the epithelioma, it is the most frequent tumor of the digestive tract. The lymphosarcomas of the gastrointestinal tract observed by the authors presented a localized form, a diffuse and multiple form with acute and chronic leucemia, a transitional form of mixed variety and acute or chronic leucemia of lymphoid or myeloid type.

From a pure anatomic point of view the gastric lymphosarcomas were classified in the following varieties: diffuse infiltrating ulcerative, polypoid multiple nodular and mixed. Some lymphosarcomas cause a peculiar form of the small intestine (more rare in the colon) with dilatation to form a sac at the site of the tumor which gives the appearance of an aneurysm. Microscopically the gastrointestinal sarcomas presented 3 distinct histological types: lymphocytic, lymphoblastic, and reticular depending upon which cells predominate.

As far as the diagnosis is concerned, 3 cases were found with manifest tumoral lesions of the stomach and intestine months after peripheral adenopathy had been discovered.

The radiologic characteristics of these tumors is discussed in detail.

The gastric localization presented itself under two modalities: the localized and the diffuse and multiple types. The first is confused systematically with carcinoma and ulcer; there is thickening of the submucosa with or without ulceration. In necrotic lesions there is no sharp limitation of the borders of the lesion. In the roentgenogram the diffuse and multiple variety presents not only the principal infiltrating tumor

which no amount of medical therapy can benefit. Thirty patients had undergone one or more surgical operations previously for complications of peptic ulcer.

Usually the indications for resection were multiple, but in 39 cases the primary indication was pain. In 30 cases, obstruction. In 19 cases, bleeding. In 7 cases, gastric ulcer without healing. In 7 cases, wrong diagnosis. In 1 case perforation and in 1 case gastrojejunocolic fistula. Gastric resection was not considered for the ulcer patient who was able to carry on full time work and whose condition could be well controlled with medical therapy.

At operation 70 duodenal ulcers, 21 gastric ulcers, 5 marginal ulcers and 1 gastrojejunocolic fistula were found. Ten patients had multiple ulcers. A walled off perforated ulcer was present in 59 per cent of the patients.

Preoperative and postoperative gastric acidity were studied and the average preoperative value was shown to be 50 U at 60 minutes. After surgery the average value was 5. In attempting to correlate the amount of stomach resected with the reduction of free hydrochloric acid a greater percentage of patients with achlorhydria was found among those with a two-thirds resection than among those with a three-fourths resection. The authors offer the explanation that the shorter afferent loop in the two-thirds resections may account for the above finding.

All gastrojejunal anastomoses were of the termino-lateral, oralis totalis type. 99 were retrocolic. An associated enterocystostomy was performed in 5 cases, 3 of which were of the en y type after partial jejunal resection for marginal ulcer. Pyloric exclusion was performed in 4 cases only, which reflects the authors' opinion that the so-called "irremovable" duodenal ulcers are not common.

Thirty-one per cent of the patients had nonfatal postoperative complications. In 9 cases there was pulmonary involvement. In 5 cases wound infection and in 3 delayed function of the anastomosis. Obstructed anastomosis, incomplete intestinal obstruction, laryngeal edema, pancreatic fistula, jaundice, wound separation, evisceration, intra-abdominal abscess, ascites, and bleeding from the gastrointestinal tract were other complications.

There were 8 deaths. Of these 5 occurred among patients in whom less than two-thirds of the stomach had been removed. It would appear that the magnitude of the resection per se does not increase the mortality rate. Two patients died because of cardiac failure and 6 died of peritonitis due to a breakdown of suture lines, damage to the bile ducts, and wound infection. Case reports are presented of the 8 cases in which death occurred. From these the authors conclude that:

1. A patient who has lost large amounts of blood over a period of time is a poor operative risk even though supported by many transfusions. Earlier operative intervention before succeeding exsanguinating hemorrhages will give a lower operative mortality.

2. Gastric resection may be indicated even though the patient has severe heart disease if symptoms are severe enough.

3. Improvements in technique of pyloric stump closure may obviate the difficulty in obtaining a secure closure of the antral mucosa.

4. Poor healing is definitely related to a great blood loss and is responsible for separation of suture lines and fatal peritonitis.

Ninety-two patients were available for follow-up studies. Of these, 51 were examined later at the hospital and 7 were followed by letters. Using rather strict criteria the authors found that 51 of the 59 patients were well, 4 were improved, and 4 had a recurrence. There was no evidence of recurrence in the 33 patients who were followed indirectly.

Studies of the 4 recurrent cases showed the presence of high gastric acidity. The authors believe a relative achlorhydria is necessary to prevent recurrent ulcer. It was believed that removal of an inadequate amount of the stomach was the cause of recurrence in 3 cases. In the remaining 1 case, marginal ulcers were resected with re-establishment of continuity by the en y type of jejunostomy and recurrence was blamed on this type of anastomosis. Secretin is not produced because it is impossible for acid gastric juice to reach the duodenal mucosa. The buffering effect of bile and pancreatic juice is lost since these juices bypass the gastrojejunal anastomosis, leaving it exposed to the acid peptic digestive juice.

The authors report a direct relationship between recurrent ulcer and conservative surgery.

In the 50 patients in whom less than a two-thirds resection was done the recurrence rate was 13.3 per cent while in the 80 patients with a two-thirds or more resection the rate was 3.9 per cent. In 11 patients with ulcer which was treated by gastroenterostomy during the same period the recurrence rate was 17.3 per cent.

Case reports of the 4 patients with recurrent ulcers are given in detail.

During 1944 and 1945 121 additional gastric resections were performed for ulcer and its complications. Forty-one patients had had previous surgery for peptic ulcer. In 31 cases the indication for resection was a severe complication of peptic ulcer or of previously inadequate surgical treatment. There were 2 deaths, a 1.6 per cent mortality. The authors attribute the decreased mortality to refinements in operative technique and careful attention to pre and postoperative care. Two-thirds of the stomach was removed in a greater number of the patients in this group than in the previous group of 100. Follow-up examinations in 93 per cent of this group although short have failed to reveal any recurrent ulcers. During this same period only 2 gastroenterostomies for ulcer were performed.

During the 5 year period from 1941 to 1945 the authors report a mortality rate of 4.5 per cent the ulcer recurrence rate was 1.8 per cent.

ROBERT R. BIGGLOW M.D.

Barrett, M. K. *Avenues of Approach to the Gastric Cancer Problem. J Nat Cancer Inst* 1946, 7 197

The greater number of deaths from cancer are among patients with gastric cancer (26,000 to 40,000 yearly). Since the problem is of major importance, the author has made a study of over a thousand articles and books in an effort to find suggestions for further clinical or experimental work. Factual knowledge of the major associations and relationships of gastric carcinoma are summarized in twelve sections, as follows: Heredity, Diet and Vitamins, Hormones, Bacteriology, Gastritis, Pernicious Anemia, Achlorhydria, Ulcer, Gastric Polyps, Methods of Diagnosis, and Experimental Carcinogenesis. General suggestions are made for further study along various lines.

The most pressing need is for earlier diagnosis. With the best treatment the average percentage of 5-year survivals is but 5 or 6 per cent. The author states that only one half of all patients hospitalized or gastric cancer are operable and of these only one-half of the cancers are resectable.

Methods feasible for attaining early diagnosis in a large number of cases are not now apparent.

FRANK B. QUINN, M.D.

Wahren, H. L. *Total Resection of the Carcinomatous Stomach. Acta chir scand.*, 1947 95 193

Total gastrectomy in cases of carcinoma of the fundus and upper corpus of the stomach is advocated by the author not only because subtotal resection, *a priori* fails to fulfill the theoretical demands for radical treatment of a cancerous process, but also because of the observations of Borrmann and of Eker who showed that cancer cells could be demonstrated in tissue as far as 5 cm. from the palpable tumor but appeared to be healthy macroscopically. According to various authors lymphatic metastases occur in from 36 to 75 per cent of the cases of ventriculo-carcinoma.

Pentinitis originating in the anastomosis between the esophagus and the jejunum and/or the duodenum is probably the most usual cause of death following total gastrectomy. For this reason the author carefully preserves the ascending branch of the left gastric artery upon which the lower portion of the esophagus is dependent for its nutrition to a high degree, although such a maneuver lessens the possibility of effectively removing the lymphatics in the region of the cardia.

A technique of total gastrectomy and esophago-jejunojejunostomy through a subcostal upper left abdominal incision is described. Section of both vagi and incision of the peritoneum anteriorly and posteriorly over the abdominal esophagus allows the surgeon to elongate the subdiaphragmatic portion of the esophagus some 5 to 7 cm. without too much traction. The esophageal stump is closed with steel wire and folded upward so that an anastomosis to the jejunum may be affected on its posterior surface. The author believes that extirpation of the spleen along with ventriculectomy as recommended by some

American surgeons, is irrational. Protein derivatives are given intravenously during the immediate post-operative phase.

Nine cases of total gastrectomy for carcinoma of the corpus are reviewed. All of the patients were discharged from the hospital in good condition. One patient was living 10 months after the operation but showed evidence of metastasis to the liver. Three patients died in from 4 to 14 months of liver metastasis and 1 other patient died after 4.5 months but the cause of his death was not determined. The 4 remaining patients are living from 1 to 2 years postoperatively and are apparently well.

WAYNE CAMERON, M.D.

Puente Duany N. and Elizondo Martel G.: *Radiologic Aspects of Gastrointestinal Lymphosarcoma—Lymphoblastoma (Aspecto radiológico del linfocarcinoma—linfoblastoma—gastrointestinal)*. *Arch. cubanas cancerol.* 1946, 5 361

Puente Duany and Elizondo Martel have made a very comprehensive clinical and radiological study of 13 cases of lymphosarcoma of the gastrointestinal tract. Twelve of the lesions were located in the intestine, 10 in the stomach and 2 affected both segments. The article is illustrated by a large number of x-ray reproductions and drawings of the different lesions found. Lymphosarcoma was found more frequently in the intestine, especially in the ileocecal valve than in the stomach. With exception of the epithelioma, it is the most frequent tumor of the digestive tract. The lymphosarcomas of the gastrointestinal tract observed by the authors presented a localized form, a diffuse and multiple form with acute and chronic leucemia, a transitional form of mixed variety and acute or chronic leucemia of lymphoid or myeloid type.

From a pure anatomic point of view the gastric lymphosarcomas were classified in the following varieties: diffuse infiltrating, ulcerative, polypoid, multiple nodular and mixed. Some lymphosarcomas cause a peculiar form of the small intestine (more rare in the colon) with dilatation to form a sac at the site of the tumor which gives the appearance of an aneurysm. Microscopically the gastrointestinal sarcomas presented 3 distinct histological types: lymphocytic, lymphoblastic, and reticular depending upon which cells predominate.

As far as the diagnosis is concerned, 3 cases were found with manifest tumoral lesions of the stomach and intestine months after peripheral adenopathy had been discovered.

The radiologic characteristics of these tumors is discussed in detail.

The gastric localization presented itself under two modalities: the localized and the diffuse and multiple types. The first is confused systematically with carcinoma and ulcer; there is thickening of the submucosa with or without ulceration. In ulcerated lesions there is no sharp limitation of the borders of the lesion. In the roentgenogram the diffuse and multiple variety presents not only the principal infiltrating tumor

which no amount of medical therapy can benefit. Thirty patients had undergone one or more surgical operations previously for complications of peptic ulcer.

Usually the indications for resection were multiple, but in 39 cases the primary indication was pain in 20 cases, obstruction in 19 cases, bleeding in 7 cases, gastric ulcer without healing in 7 cases, wrong diagnosis in 1 case, perforation and in 1 case gastrojejunocolic fistula. Gastric resection was not considered for the ulcer patient who was able to carry on full time work and whose condition could be well controlled with medical therapy.

At operation 70 duodenal ulcers, 21 gastric ulcers, 5 marginal ulcers and 1 gastrojejunocolic fistula were found. Ten patients had multiple ulcers. A wall-off perforated ulcer was present in 59 per cent of the patients.

Preoperative and postoperative gastric acidity were studied and the average preoperative value was shown to be 50 U at 60 minutes. After surgery the average value was 5. In attempting to correlate the amount of stomach resected with the reduction of free hydrochloric acid, a greater percentage of patients with achlorhydria was found among those with a two-thirds resection than among those with a three-fourths resection. The authors offer the explanation that the shorter afferent loop in the two-thirds resections may account for the above finding.

All gastrojejunal anastomoses were of the termino-lateral, orals totalis type. 99 were retrocolic. An associated enterostomy was performed in 5 cases, 3 of which were of the en y type, after partial jejunal resection for marginal ulcer. Pyloric exclusion was performed in 4 cases only, which reflects the authors' opinion that the so-called irreparable duodenal ulcers are not common.

Thirty-one per cent of the patients had nonfatal postoperative complications. In 9 cases there was pulmonary involvement, in 5 cases wound infection and in 3 delayed function of the anastomosis. Obstructed anastomosis, incomplete intestinal obstruction, laryngeal edema, pancreatic fistula, jaundice, wound separation, evisceration, intra-abdominal abscess, ascites, and bleeding from the gastrointestinal tract were other complications.

There were 8 deaths. Of these 5 occurred among patients in whom less than two-thirds of the stomach had been removed. It would appear that the magnitude of the resection per se does not increase the mortality rate. Two patients died because of cardiac failure and 6 died of peritonitis due to a breakdown of suture lines, damage to the bile ducts, and wound infection. Case reports are presented of the 8 cases in which death occurred. From these the authors conclude that:

1. A patient who has lost large amounts of blood over a period of time is a poor operative risk even though supported by many transfusions earlier operative intervention before succeeding exsanguinating hemorrhages will give a lower operative mortality.

2. Gastric resection may be indicated even though the patient has severe heart disease if symptoms are severe enough.

3. Improvements in technique of pyloric stump closure may obviate the difficulty in obtaining a secure closure of the atrial mucosa.

4. Poor healing is definitely related to a great blood loss and is responsible for separation of suture lines and fatal peritonitis.

Ninety-two patients were available for follow-up studies. Of these 32 were examined later at the hospital and 7 were followed by letters. Using rather strict criteria, the authors found that 31 of the 59 patients were well, 4 were improved, and 4 had a recurrence. There was no evidence of recurrence in the 33 patients who were followed indirectly.

Studies of the 4 recurrent cases showed the presence of high gastric acidity. The authors believe a relative achlorhydria is necessary to prevent recurrent ulcer. It was believed that removal of an inadequate amount of the stomach was the cause of recurrence in 2 cases. In the remaining 2 cases, marginal ulcers were resected with re-establishment of continuity by the en y type of jejunostomy and recurrence was blamed on this type of anastomosis. Secretin is not produced because it is impossible for acid gastric juice to reach the duodenal mucosa. The buffering effect of bile and pancreatic juice is lost since these juices bypass the gastrojejunal anastomosis, leaving it exposed to the acid peptic digestive juice.

The authors report a direct relationship between recurrent ulcer and conservative surgery.

In the 50 patients in whom less than a two-thirds resection was done, the recurrence rate was 23.3 per cent while in the 86 patients with a two-thirds or more resection the rate was 5.9 per cent. In 21 patients with ulcer which was treated by gastroenterostomy during the same period the recurrence rate was 27.3 per cent.

Case reports of the 4 patients with recurrent ulcers are given in detail.

During 1914 and 1915 121 additional gastric resections were performed for ulcer and its complications. Forty-one patients had had previous surgery for peptic ulcer. In 31 cases the indication for resection was a severe complication of peptic ulcer or of previously inadequate surgical treatment. There were 2 deaths, a 1.6 per cent mortality. The authors attribute the decreased mortality to refinements in operative technique and careful attention to pre- and postoperative care. Two-thirds of the stomach was removed in a greater number of the patients in this group than in the previous group of 100. Follow-up examinations in 92 per cent of this group, although short, have failed to reveal any recurrent ulcers. During this same period only 2 gastroenterostomies for ulcer were performed.

During the 5 year period from 1911 to 1915 the authors report a mortality rate of 4.5 per cent the ulcer recurrence rate was 1.8 per cent.

From a pure anatomic point of view the gastric lymphosarcomas were classified in the following varieties: diffuse infiltrating, ulcerative, polypoid, multiple nodular and mixed. Some lymphosarcomas cause a peculiar form of the small intestine (more rare in the colon) with dilatation to form a sac at the site of the tumor which gives the appearance of an aneurysm. Microscopically the gastrointestinal sarcomas presented 3 distinct histological types: lymphocytic, lymphoblastic, and reticular depending upon which cells predominate.

As far as the diagnosis is concerned, 3 cases were found with manifest tumoral lesions of the stomach and intestine months after peripheral adenopathy had been discovered.

The radiologic characteristics of these tumors is discussed in detail.

The gastric localization presented itself under two modalities: the localized and the diffuse and multiple types. The first is confused systematically with carcinoma and ulcer; there is thickening of the submucosa with or without ulceration. In ulcerated lesions there is no sharp limitation of the borders of the lesion. In the roentgenogram the diffuse and multiple variety presents not only the principal infiltrating tumor

but also polypoid areas, ulcer and thickening of the folds of the mucosa. The hypertrophy of the mucosa is different from that in hypertrophic gastritis. In the latter condition the folds are more regular, less thick, and not accompanied by areas of tumoral infiltration. The roentgenologic aspects of these tumors in the duodenum, jejunum, ileum and colon are illustrated. Some of the lesions, especially those of the diffuse type, may appear in the first stages of lymphoid or myeloid leucemias of the acute or chronic variety but they are more common in the late stages. The importance of x ray therapy in the treatment of these tumors is emphasized. WILLIAM E. RICKERTS, M.D.

Klefer, E. D., and McKell, D. McC., Jr.: Peptic Ulcer in the Aged. *J Am Med Ass* 947 33 1955

It is a widespread clinical impression that peptic ulcer is predominately a disease of the young or middle aged and that it occurs comparatively infrequently in elderly patients. The authors quote statistics to show that this disease is proportionally as common in the elderly as in the young or middle aged. This article is based on a study of 158 patients over the age of 65 years in whom the diagnosis of peptic ulcer was made. In this series there were 11 duodenal, 36 gastric, and 4 postoperative ulcers.

Seventy-seven of these patients approximately one-half of the series, had their first symptoms of ulcer after their sixtieth birthday and 24 after their seventieth birthday. An analysis of the remaining 67 patients who had symptoms for over 5 years revealed that a very high proportion had moderate or severe symptoms. These elderly patients with a long history of symptoms were very prone to have a chronically perforated or calloused ulcer which was very resistant to treatment. The history of these elderly patients was often atypical as only 45 per cent of them had a history that could be considered characteristic of peptic ulcer.

In general the treatment of these patients followed routine lines. Malnutrition was especially common and weight loss was often marked. The diet in cases of this type should contain adequate protein, and fat may be used sparingly; the usual milk and cream mixture may be replaced by milk in many cases. Caution should be used in the use of soluble alkalies because of the danger of alkalosis in the presence of impaired renal function.

Organic obstruction requiring surgical treatment was quite common. Seventeen of the 158 patients with duodenal ulcer required gastroenterostomies for the relief of their obstructive symptoms. Gross hemorrhage is a particularly serious problem in this age group. The authors prefer a short period of sedation and fasting for from 24 to 48 hours before feedings are instituted. Of the 158 patients, 48 gave a history of hemorrhage and 17 had repeated hemorrhages. All patients were treated medically; no operative intervention for acute hemorrhage was carried out in this series and there were no immediate deaths. However, follow up studies showed a high

incidence of late recurrent hemorrhages after treatment, and in 4 instances the recurrent hemorrhage was fatal.

Except for the complication of hemorrhage the prognosis of peptic ulcer in this age group is about the same as for ulcer in any other age group. There was a recurrence rate of 33 per cent. 107 patients obtained complete relief; 28 were benefited but had recurrences and 4 were not benefited. Eight of these patients died as a result of their ulcer, of these 4 died because of hemorrhage, 1 of perforation, 3 died after operation and 1 died at home, the cause not being ascertained. Eighteen gastroenterostomies and 9 subtotal gastric resections were performed with 3 deaths.

The authors believe the only dependable proof of the benignity of an ulcer is to have it completely disappear under treatment.

F. J. LEBENHART, JR., M.D.

Kimble, S. T., Jr.: Protein Hydrolysate Therapy for Peptic Ulcers: Preliminary Report. *Gastroenterology* 1947 8 467

Considerable interest in the value of protein hydrolysate in treating peptic ulcer has been aroused since Co Tui's report in July 1945. His results in a series of 30 patients were so suggestive that additional study of the merit of this therapeutic technique was planned.

The author reports the results in a series of 15 ulcer patients treated with a 6 per cent solution of protein hydrolysate administered by gastric drip and venoclysis.

The protein hydrolysate is a heat-sterilized, stable pyrogen free, enzymatic derivative of beef. It contains no undigested proteins or proteoses, and a liter of the 6 per cent solution is equal to 60 gm. of protein.

The administration of protein hydrolysate varied from patient to patient. No therapy was instituted without x ray proof of the presence of an ulcer. In 11 cases the protein hydrolysate was administered by continuous drip through a Levine tube left in place in the stomach for 7 days. Five hundred cubic centimeters of hydrolysate were alternated with 600 c.c. of milk and cream, so the patient received 1,500 c.c. of hydrolysate (90 gm.) of protein and 1,800 c.c. of milk and cream in 24 hours.

Five patients were given the continuous drip for 7 days and then given venoclysis of protein hydrolysate (500 c.c. three times a day) for 3 or 4 days. One patient with hemorrhage on admission received 10 days of drip treatment followed by venoclysis. Four patients were given hydrolysate by vein alone (1,500 c.c. daily) supplemented with 3 oz. of milk and cream hourly during the day.

These patients received 143 gm. of protein daily by gastric drip and 126 gm. when the hydrolysate was administered by venoclysis, supplemented by milk and cream. As this was almost 3 times the daily protein requirement, these patients were assumed to be in positive nitrogen balance.

The emphasis was placed upon control of ulcer rather than cure. Patients were allowed bathroom

privileges smokers were allowed 6 cigarettes daily. Supplementary medications varied. Phenobarbital, belladonna, and ascorbic acid (200 mgm. daily) were routine. Sodium amyltal was given for sleep. Liver, iron, vitamins given orally and parenterally and transfusions were prescribed for hemorrhaging patients. After removal of the tube bland feedings were alternated with milk and cream.

In this study 13 patients had duodenal ulcers, 1 gastric ulcer alone and 1 combined duodenal and gastric ulcers. Nearly all possessed the physical and emotional characteristics of the ulcer type. The ages averaged 44 years with 30 and 69 being the extremes. There were 12 white males, 1 white female and 1 colored male in the series. Epigastric distress was the outstanding symptom in all cases and was present from 4 days to 15 years. Four patients had severe hemorrhage and 1 intractable vomiting before treatment. No patient had had previous surgery. Six had been treated unsuccessfully by bed rest and the Sippy diet.

Three complete case histories are given.

X ray check up studies were performed immediately after treatment with the hydrolysate was completed. In 9 cases the ulcer deformity had completely disappeared. Five cases showed marked improvement and 1 of these was completely healed 11 weeks later. Only 1 case failed to improve. In general, the higher the age of the patient and the longer the length of the ulcer history the more delay in healing.

The patients with hematemeia had no further bleeding after treatment was instituted. The one failure was believed to be due to an elevated histamine level accompanying an allergic state.

The total serum protein in 11 cases before therapy averaged 5.3 gm. per cent. After therapy the average was 6.9 gm. per cent. The average weight gain of 12 patients was 13½ pounds.

All but 1 of the patients were rendered completely free of ulcer symptoms during treatment. This was accomplished in from 12 to 96 hours.

Side reactions in administering 205 liters of protein hydrolysate were infrequent. When they were observed vomiting, frontal headaches, facial flush and nausea were usually due to running the effusion too fast.

Follow up studies are not complete but no case in which x ray evidence of ulcer completely disappeared had a recurrence. Only one of the patients is having symptoms, and these are mild. It is believed that protein hydrolysate is effective in treating the ulcer patient because it neutralizes gastric acid and adds to the supply of body protein. Follow up and control studies are being undertaken to confirm the long range value of this method of peptic ulcer therapy.

ROBERT R. BUCKLOW, M.D.

Hodges, H. H.: Protein Hydrolysate Therapy for Peptic Ulcer; a Report on 26 Cases. *Gastroenterol.* 33: 1947: 8-476.

Protein hydrolysate apparently has a beneficial effect in the treatment of peptic ulcer as reported by

Co-Tsu, Schenker and Clark and Vincl. It has been used in several different ways but its beneficial effect seems to be due to its buffering action and high nitrogen intake. The author presents this report as a critical evaluation of the effectiveness of oral administration of a protein hydrolysate in the treatment of chronic peptic ulcer and makes observations pertaining to nutrition and metabolism in human subjects whose sole source of dietary nitrogen was predigested protein.

Since February, 1946, 26 patients were selected for this study particularly on the basis of the chronicity of their ulcers. This group had failed to respond to the conventional dietary therapy on an ambulatory basis. Twenty three patients were hospitalized for the entire course of treatment and 1 patient was treated entirely as an outpatient. Hospitalized patients were allowed as much activity as they desired throughout the treatment period.

Twenty were males and 6 females; their ages ranging from 18 to 65 years. Eighteen had duodenal, 4 gastric and 3 stomal ulcers and 1 had an esophageal ulcer. The symptoms had been present from 4 months to 32 years. Five patients had prolonged gastric retention, 2 had vomiting, 3 recent evidence of bleeding and 5 clinical or x ray evidence of impending perforation.

A diagnosis of active ulcer was clearly indicated in all cases. In 23 cases this was confirmed by x ray studies and in 1 case by gastroscopy. In all but 3 cases follow up x ray studies were carried out after treatment for from 14 to 21 days.

The therapy consisted of frequent administration (at least every 2 hours) of an equal mixture of a proteolytate and dextrimaltose given daily. The average patient ingested 750 gm. of this mixture which yielded 285 gm. of protein, 2900 calories and 7.5 gm. of sodium chloride. The proteolytate is an enzymatic hydrolysate of casein. The dextrimaltose supplies only carbohydrate and calories.

Except in 4 instances no other food material was allowed during the treatment period of 14 to 21 days. Adequate vitamin supplements were provided routinely.

Complete relief of symptoms was obtained in 23 patients in an average of 4.4 days. In the remaining 3 patients the condition failed to respond or became worse. The treatment was discontinued after 2, 10 and 6 days, respectively.

In 12 of the 23 patients who became asymptomatic there was no roentgen evidence of ulcer activity after the 2 to 3 week treatment period and in 8 there was marked improvement but with some residual irritability or deformity without a crater. In 3 there was no x ray evidence of improvement.

A weight gain was usual the average being 4.5 pounds. Ten of 11 patients showed a diuresis during the last few days of treatment. Most patients showed a rise in the blood urea nitrogen levels but the serum protein and hemoglobin changes were constant. After treatment the degree of gastric acidity tended to be reduced. Individual feeding of

the mixture completely neutralized free gastric acid for an average of 70 minutes.

One patient suffered a serious gastrointestinal hemorrhage on the tenth day of treatment. Two patients suffered a mild diarrhea.

Although the taste of the hydrolysate is unpleasant no real difficulty was encountered on that account. The mixture did not seem to satisfy the normal sensation of hunger.

Of the 20 patients with x ray evidence of healing or improvement 5 had recurrence of the ulcer symptoms within 1 to 5 months. One patient was subjected to resection because of pyloric obstruction. Fourteen patients were asymptomatic for from 1 to 8 months. The 3 with no x ray evidence of improvement had prompt return of the ulcer symptoms and they as well as the 3 who failed to respond symptomatically were subjected to operation.

Evaluation of the results from the hydrolysate therapy is difficult and largely a matter of clinical impression. Three failures occurred in the 26 patients, although in the majority this treatment was more efficacious than a conventional dietary program in producing a remission. In several instances (1 case of esophageal ulcer) the prompt relief of symptoms and x-ray evidence of healing or disappearance of retention was dramatic.

It was the author's opinion that the frequency of relapses in ulcer patients was not diminished by this therapy. It is believed that the protein hydrolysate may become a useful adjunct to medical management of peptic ulcer particularly when surgery is contraindicated or as a therapeutic test for malignancy. However the expense of the present commercial preparations and the necessary vitamin supplements will preclude its routine use in most cases.

ROBERT R. BRIDLOW, M.D.

Trinca, A. J.: The Treatment of Acute Perforation in Peptic Ulcers. *Med. J. Australia* 947 355.

Five hundred and sixty-eight cases of surgically treated acute perforations of peptic ulcers are reviewed. Recognized factors influencing the mortality in such cases are listed as the age of the patient, the duration of the perforation, the general condition of the patient and the presence of intercurrent diseases. As the main theme of his article the author lists a fifth factor influencing the mortality, the factor which varies with the surgeon, namely the particular form of surgical treatment adopted. It is the contention of the author that the high mortality rates are due largely to incorrect surgical procedures.

In considering the pathology the author points out that the peritoneal cavity is only a potential cavity without dead space. When perforation of an ulcer occurs the gastric or duodenal contents pour out and contaminate the parietal and visceral peritoneum. The result is an immediate inflammatory reaction which can be divided into three somewhat overlapping stages. The first, "the hyperemic stage" is characterized by dilatation of formerly potential capillaries in the subperitoneal zone. Following this

the exudative stage" occurs in which a reactionary exudate forms in the subperitoneal zone. In this stage the irritation of the nerve endings produces intense pain and muscular rigidity of the boardlike abdomen. The third stage is "the plastic stage" in which fibrin is deposited in varying degrees upon the inflamed surfaces. It is pointed out that the thinness or the thickness of the exudate has no relation to its virulence.

The past literature is reviewed and quoted to bear out the author's contention that there is a natural resistance of the peritoneal cavity and that the exudate in the early stages of perforative peritonitis is purposive and protective and an adjunct to the peritoneal resistance. The exudate is antacid and antibacterial and delays absorption, and in some cases localizes the effects of infection. It is pointed out that attempts at removal of all the fluid at operation will result in increased mechanical irritation and possibly further dehydration of the patient. The bacterial peritonitis of the subperitoneal zone is inaccessible for drainage.

The literature is further reviewed to bear out the author's contention that for purely mechanical reasons the entire peritoneal cavity cannot be satisfactorily drained. The author suggests that the old dictum "When in doubt drain," should be altered to "When in doubt do not drain." The evil effects of the drainage tube are listed as (1) the production of duodenal, gastric, or ileal fistulas, (2) the production of ileus, (3) acute intestinal obstruction, (4) increased incidence of complications particularly subphrenic abscess and pneumonia, (5) delayed convalescence, (6) incisional hernia, and (7) late delayed intestinal obstruction from adhesions.

In the discussion of treatment the author contends that many of the fatalities could have been avoided by the adoption of proper preoperative treatment including the administration of fluids and the relief of pain. It is pointed out that bacterial peritonitis is a comparatively late manifestation and that operation can be deferred for periods up to 12 hours, if necessary to improve the patient's condition. The author states that he uses and prefers gas anesthesia because it produces less anesthetic shock and is less likely to produce pulmonary complications. He thinks that spinal anesthesia may also be used satisfactorily.

At operation the author prefers to use a simple, effective method of closing the perforation. A tag of omentum is isolated looped with a tie of 0 or 00 chromicized catgut, the two free ends of the gut are then threaded on curved needles and these are each passed into the perforation and back out through the gastric or duodenal wall. The suture is tied over the peritoneal surface and the plug of omentum is then introduced into the perforation. Extra sutures are placed about the margin of the omental tag affixing it to the serosal surface. Enough of the exudate is removed to render the perforation visible. Visible particles of food are removed. The author is convinced that the leaving of exudate is not the essential cause of residual abscess formation. Two indications

for the use of a drainage tube are listed namely (1) the inability to locate the perforation at operation and (2) the presence of a localized collection of pus such as in subphrenic abscess.

In addition to the above mentioned points in treatment, the author states that patients can be further benefited by the preparation of a culture from the exudate and the use of appropriate chemotherapeutic measures to combat infection if peritonitis is well established. Modern methods to maintain fluid balance, promote retention of chlorides and to relieve intestinal distention should be adopted.

The statistics presented show that the mortality rate in the cases with drainage was more than 3 times as great as that in the cases without drainage. Factors such as age and duration of the perforation did not invalidate the statistics but further strengthened the case against drainage. Complications were shown to be 3 times as great when drainage was used. The average stay in the hospital was half as long again with drainage. W. FOSTER MONTGOMERY M.D.

Thompson Harold Lincoln; and Prout, Harry: Surgical Treatment of Peptic Ulcer; Recent Experience at Los Angeles General Hospital. *Arch. Surg.* 1947 54 390

The authors present an exhaustive and detailed study of the surgical treatment of peptic ulcer as carried out during the latter part of the war years at the Los Angeles General Hospital.

It is noteworthy that during this period only 22 per cent of the patients with peptic ulcer were treated surgically. This figure includes cases of acute perforation and indicates that a relatively small proportion of routine peptic ulcer patients require surgery.

Röntgenologic examination was an adjunct diagnostic aid of considerable value although in 8 per cent of the cases there was an x ray diagnostic error.

The authors note that in 6 simple or uncomplicated cases of peptic ulcer radical gastric resection was performed with a mortality of 50 per cent. A more careful evaluation of the operative attack and the pathologic status of the ulcer is suggested and this is important in a hospital where a large number of surgeons are engaged in the treatment of "service cases." An over-all surgical mortality rate of 19.3 per cent is reported. This figure is considered in the light of civilian surgery performed at a charity hospital during wartime conditions. Not only was the type of patient different during the war but a serious shortage of surgical and nursing services greatly aggravated a difficult situation.

The statistics given are shown by means of graphic designs and pictures. EDWARD F. LEWIS M.D.

Lagos García Alberto; and Díaz Bobillo, Manuel U: Complete Volvulus of the Small Intestine in the Newborn (Vólvulo total del intestino delgado en el recién nacido). *Sem. méd.*, B. Air., 1947 54 341

The study of volvulus in the newborn is intimately related to the anomalies of the embryological devel-

opment of the small intestine, as this constitutes the predominating factor in intestinal torsion.

The authors report a case of complete volvulus of the entire small intestine occurring in a two day old female who persistently vomited an abundant amount of bile stained fluid. Loss of weight and constipation were present. On physical examination a poorly nourished, poorly developed and dehydrated baby was seen. The fontanelles were sunken the abdomen was globular in shape, with visible peristaltic waves traveling from left to right in the epigastrium. A flat plate roentgenogram revealed an excessive quantity of gas in the small intestine, while, after the ingestion of a barium meal, one could see a dilatation of the stomach and first portion of the duodenum, with a retention after 48 hours. A barium enema showed the ascending colon and cecum located under the transverse colon.

Preoperatively the patient was prepared with plasma, saline and glucose, and a gastric lavage. Under ether anesthesia a right paramedian incision was made supraumbilically and the peritoneal cavity was entered. A small amount of milk-colored fluid escaped signifying a probable block of the lymphatics. The cecum and ascending colon was found beneath the transverse colon. Although a complete volvulus of the small intestine was found the color was normal. The small bowel was rotated over 360 in the opposite direction of its twist, and the abdomen was closed. Postoperatively there was no vomiting and the patient gained weight.

Of great importance in the diagnosis of volvulus in the newborn is the x ray findings, which are as follows: (1) dilatation of the gastric portion, and first and second parts of the duodenum (2) complete or partial obstruction at the level of the third part of the duodenum and (3) the duodenum is located entirely to the right of the midline which implies an anomaly of intestinal rotation. A barium enema is likewise important as it may show an abnormal position of the cecum in the epigastrium or right hypochondrium.

Conditions to be differentiated although they likewise are surgical are hypertrophic pyloric stenosis, annular pancreas stenosis and congenital atresia of the duodenum. ANTONIO F. CIPOLLA, M.D.

Rosenak, S. and Hollander, F. Early Postoperative Motor Response of the Small Intestine to Jejunal Feedings. *Surg. Clin. N. America*, 1947 27 343

The purpose of the present study was to evaluate the small bowel motility in jejunostomy patients during the first 2 days following operation. Intra-jejunal alimentation in surgery of the gastrointestinal tract is a major factor in improving the early postoperative nutritional status of the patient, and thereby influencing the convalescent state and power of tissue repair.

Of importance in the increased use of surgical jejunostomy and orojejunal intubation is the recent improvement in the type of feeding mixtures em-

ployed for this purpose. A newer predigested synthetic aliment advocated by the authors has eliminated in great part the diarrhea, cramps, and other gastrointestinal disturbances associated with the administration of earlier types of jejunostomy feeding mixtures. The authors also stress the important point that whenever jejunostomy is performed for alimentation, the feedings should be instituted as soon after operation as physiological considerations permit.

If a physiologic precept that during the first few days after abdominal operations patients suffer some impairment in the threefold functions of the gastrointestinal tract, namely secretion, absorption, and motility. The authors: a series of long term studies are attempting to determine whether or not the extent of such physiologic impairment is great enough to invalidate the use of intrajejunal feeding during the early postoperative period.

In order to study the motor activity of the gastrointestinal tract a series of x-rays were taken of patients with surgical jejunostomy. It was the objective of the study to determine whether the massive introduction into the jejunum of 100 c.c. of aliment (with barium added) is normally transported at a rate sufficient to permit its routine administration. All conditions were carefully controlled and x-rays were taken at 1, 2, and 3, from 5 to 10, and from 20 to 24 hours following the injection. Control studies were repeated from 3 to 5 weeks after operation.

In interpreting the results of this study the authors indicate that the time normally required for chyme to travel through the small bowel is highly variable and subject to influence by medication and many other factors. However they conclude that jejunal feedings with their predigested synthetic aliment may be instituted as early as 24 hours postoperatively provided certain precautions are taken. The absence of retrograde movement of the aliment as shown by x-ray visualization indicates that this feeding procedure does not jeopardize the intactness of the duodenal stump.

During the early days following operation the administration of jejunostomy aliment is safe if special precautions are taken regarding the volume and rate of administration. Low and F. LEWIS, M.D.

Booher, R. J. and Pack, G. T. Cysts of the Duodenum. *Arch Surg* 1946, 53, 584

The authors report two types of duodenal cyst: a true enterogenous cyst of the duodenum and a cyst of Brunner's glands. This situation is rarely reported in the literature. Including the cases in this report there have been 13 cases of enterogenous cysts of the duodenum described since the initial case of Sanger and Klopff in 1880. Of the cases reported, 2 occurred in males and 8 in females, and in 2 there were no records of sex. The ages of the patients varied from newborn to 17 years.

The incidence of duodenal cysts. Low. Robertson found 2 instances of cystic dilatation of Brunner's glands in gross examination of 15,000 cases. Ackerman reported the incidence of diverticula of the duo-

denum discovered at autopsy as varying from 3.3 per cent of 1,367 cases (Leinsmeyer) to 15.5 per cent (Schuppel) and an incidence on roentgenologic examination varying from 0.016 per cent of 72,715 cases (Rankin and Martin) to 5.19 per cent of 770 cases (Cryderman). He found an even higher incidence by making plaster molds of the duodenum of cadavers—11 diverticula in 50 consecutive cases or an incidence of 22 per cent. Yet he made no mention of finding the embryologic counterpart or sequela, i.e. an enteric cyst. Pachman reviewing 36 cases of enterocyst found 28 cases of cysts of the terminal ileum or ileocecal area as compared with 8 in the duodenum. Ladd and Gross, in 1940, reported 18 patients with cystic lesions in various parts of the intestinal canal but only 1 cyst was in the duodenum.

Robertson, discussing the degeneration and infiltration of Brunner's glands, states that the outstanding characteristic of the glands is their comparative freedom from influences which ordinarily affect secreting tissues. Occasionally there is stasis of secretion with dilated ducts and acini. In some cases this is evidently because of obstruction to the duct. It has been observed in the region of invading or metastatic tumor nodules and on the margin of chronic or healed ulcers. Such a condition may lead to cyst formation in which acini or even an entire lobule may be dilated and contain a mass of cell detritus mixed with varying amounts of mucus. These cysts are lined with low cuboidal cells, and the cavities are largely free from stainable substances.

There are several theories of causation of enterogenous cysts. Lewis and Thyng concluded that "knoblike" diverticula occur regularly in the embryo and that they usually degenerate and some times formed detached cysts and nodules. It was believed that these structures might give rise to pathologic diverticula. Orgias concluded that the cyst is a developmental cyst of the duodenum and has developed as a diverticulum of the first part of the duodenum. Evans concluded that because these cysts reproduce the structure of the bowel they are derived from the gut and are developmental. Hughes-Jones proposed the theory of epithelial sequestration as a possible origin. The authors make the statement that if these "knoblike" diverticula or misplaced or displaced enteric anlagen, are the source of origin for both cysts and diverticula, it is surprising that primary diverticula of the duodenum are so frequent and cysts so uncommon.

By definition, the walls of these cysts correspond to the structure of the intestinal canal. They present well defined muscular coats and glandular linings, and although intracystic pressure may cause atrophy and flattening of the glands, the glands of Brunner are apparent.

Enterogenous cysts may occur anywhere in the wall of the bowel or in the mesentery and are classified as submucosal, intramucosal, subperitoneal and intra-mesenteric. They have occurred most frequently in the second portion of the duodenum but

have extended up to the pylorus and have arisen behind the first portion. The size has varied from the size of a walnut to that containing 500 c.c. of fluid. The average size has been between 6 and 7 cm. in diameter.

All patients with enterogenous cysts have present signs and symptoms of duodenal obstruction. Persistent vomiting or regurgitation has been a predominant symptom occurring with pain in 3 cases. In 9 a tumor had been palpable. According to Gardner and Hart the most important diagnostic signs were palpable tumor and signs of duodenal obstruction. Ladd and Gross observed that most cysts of the duodenum jejunum and ileum brought early signs of intestinal obstruction, characterized by colicky pain, vomiting, increased peristalsis and finally signs relating to dehydration. Cysts of Brunner's glands are usually asymptomatic.

Röntgenologically the findings vary from none to a round central filling defect of the second portion of the duodenum but with nothing characteristic to differentiate it from papilloma or polypoid benign tumor of the wall.

Treatment consists in surgical removal. This is effected in 2 of 4 ways: (1) duodenal resection with the adjacent cyst; (2) enucleation or excision; (3) simple evacuation or (4) marsupialization. In the authors' case the cyst was successfully enucleated. This procedure cannot be carried out without difficulty because of the lack of a good line of cleavage and the dangers of perforation of the viscus or laceration of the wall and transverse closure of the duodenostomy in the longitudinal plane relieved the fear of jeopardizing the viability of the bowel wall. Miller enucleated 10 cysts of the ileocecal region without a death.

Of the 6 survivors of the 13 collected cases, 3 have had resection of the adjacent duodenum, 3 had local excision, 1 survivor had gastrojejunostomy after drainage of the cyst and 1 had enterocystostomy with successful results. This represents an operative mortality of 45.4 per cent and a case mortality of 53.8 per cent.

Enucleation of cysts of Brunner's glands is not attended with the difficulties inherent in the management of enterogenous cysts, and simple enucleation is sufficient.

EDWIN W. PASSARELLI, M.D.

Blum, L.: Nontumid Ileocolic Intussusception in an Adult. Report of a Case with Cecal Ulcer. *Surg. Clin. A. America* 1947 27 355.

The author presents a case of nontumid intussusception in a middle aged adult and discusses the factors of pathogenesis. A brief survey of the literature reveals that between 5 and 10 per cent of all cases of intussusception occur in adults.

Most cases of intussusception in adults are associated with a bowel tumor either inflammatory or

neoplastic. The author points out that there is no disagreement as to the mechanism of this process in the presence of a tumor. The normal pattern of peristaltic activity could be expected to invaginate the mass whether intramural or intraluminal, into the segment of bowel immediately below thus initiating the process of intussusception.

However when there is no anatomic abnormality of that portion of the intestine which forms the apex of the intussusception it is not easy to formulate an acceptable etiologic theory. Since 97 per cent of all cases start near the ileocecal junction, the author mentions the following concepts of pathogenesis:

1 That the ileocecal valve normally projects through the wall of the cecum so that during the discharge of intestinal contents it telescopes into the lumen of the large gut. When due to some derangement of intestinal rhythm this may become marked the process may overreach itself and an intussusception of the usual type with the ileocecal valve as the apex can be so started.

2 That the base of the appendix due to a local inflammatory process can similarly be the initial point and drag the adjacent ileocecal valve with it as the forefront of the intussusception.

3 That the lymphoid tissue aggregates (Peyer's patches) which are of considerable size during the first year of life and may persist in an enlarged form, serve as intramural tumors and start the process in the last inch or two of the ileum.

4 That the slope of the mesentery that is the angle at which the ileum joins with the cecum may tend to precipitate invagination of the small into the large bowel, and that the reason for its predominance in the male is related to the more obtuse ileocolic angle in infants of this sex.

5 That the mesentery may be unusually long and that the peritoneum enclosing the ascending colon may be unusually lax, resulting in a mobile cecum.

The author does not mention the concept that vigorous peristalsis at the ileocecal junction is often countered by antiperistalsis in the cecum which may lead to intussusception. However he does suggest that functional derangements of the luteine can be postulated on a neurogenic basis. The ileocecal region is believed to be the junction of the vagal and sacral portions of the parasympathetic system. The writer believes that intussusception might result from disturbed peristalsis at the neural junction.

The case reported was that of a middle aged male who had a nontumid intussusception which was treated by a stage operative resection of the terminal part of the ileum, ascending colon and part of the transverse colon with recovery.

EDWARD F. LEWIS, M.D.

Pack, G. T., and Booher, R. J.: Intussuscepting Submucous Lipoma of the Right Colon. *Surg. Clin. A. America* 1947 27 361.

Something will have been accomplished by this article if the surgeon's attention will have been

directed to the possibility of the presence of intussuscepting submucous lipoma of the right colon either prior to or during operation when he is face to face with an obscure abdominal case (Stetten)

In cases of obscure abdominal pain occurring intermittently for a long time with intervening episodes of complete freedom from pain, and with signs and symptoms of transitory obstruction associated with a palpable mass especially in the right half of the colon, a tentative diagnosis of intussusception due to benign tumor may be in order

A total of 133 cases of submucous lipoma, situated in the area from and including the ileocecal valve to the rectum has been previously reported.

Two cases of submucous lipoma of the colon are reported, one tumor arising from the ileocecal valve and producing chronic obstruction on the basis of intermittent redicible intussusception, and the other arising in the ascending colon and producing intermittent transitory intussusception.

JOHN J. MALONEY M.D.

McNealy R. W. and Landa, V. G. Primary Anastomosis in the Treatment of Carcinoma of the Colon *Surgery* 947 183.

Thirty four consecutive cases of open anastomosis of various parts of the large bowel, with but 3 deaths, neither directly attributable to surgery are reported. In none was colectomy used.

There were 4 carcinomas of the right colon 3 of the transverse colon 11 of the sigmoid, 8 of the recto-sigmoid, and 1 carcinoma of the splenic flexure.

Details of the preoperative and postoperative management of both the obstructive (7) and the non-obstructive cases are presented. Close attention is given to succinylsulfaiazole prophylaxis and to protein, hemoglobin and vitamin levels "the entire problem of primary anastomosis revolves intimately about the newer concepts of adequate preoperative and postoperative management.

The operative procedures, with illustrative drawings are discussed and the use of a minimum of sutures, in two layers and well disposed, is urged.

The author believes that the low mortality, the shortened hospital stay, elimination of multiple operations, and the saving of time, expense, and psychic trauma make the primary open anastomosis the recommended operation in resectable nonobstructive carcinoma of the colon. FRANK B. QUEK, M.D.

D Allaines, F., and Carrillo-Maurtua, L.: Colectomy with Immediate Anastomosis in the Treatment of Cancer of the Left Half of the Colon (La colectomie et anastomose immédiate dans le traitement du cancer du colon gauche) *J. chir. Par* 946 6 429

For the past few years one of the authors, convinced of the disadvantages inherent in the procedure of exteriorization, endeavored to perform resections with primary anastomosis in the treatment of cancer of the left colon. These operations carried out in one or two stages are now regarded as entirely

satisfactory. Safe and comfortable, they deserve to be better known.

In order to decrease the risk of colectomy on the left side it became imperative not only to improve the technique of anastomosis but also to perform the operation in stages with either exteriorization or diversion of the fecal stream before resection was attempted.

With the number of failures steadily increasing, any method less dangerous than the colectomy of Reybard was considered very safe. The operation of exteriorization was readily accepted. Statistics published since 1934 representing 450 resections done by 13 different surgeons, reveal that the mortality rate in these operations averaged 20 per cent. Their safety therefore is more apparent than real.

It is the authors opinion that the real disadvantages of exteriorization operations are (1) the necessity of several operations, (2) the necessity of establishing a temporary colectomy for several months (this is not without risk) (3) each operation carries a certain mortality rate and (4) the operations require a prolonged hospital stay. The authors agree that exteriorization is sometimes the procedure of choice, but they believe that it is a dangerous operation.

The writers believe with Pierre Duval that colectomy in one stage means resection of the colon and re-establishment of continuity at the same operative session regardless of whether or not it is preceded by diversion of the fecal stream proximal to the suture line of anastomosis. The techniques of left colectomy in one stage are so numerous that classification is difficult.

Certain techniques of colectomy in one stage do not call for diversion of the fecal stream. The anastomosis may be exteriorized (Senèque) or simply returned to its normal place in the abdomen. The latter procedure could be called the modified operation of Reybard because the anastomosis is often side-to-side and is often aseptic. These operations require abdominal or lumbar drainage and aspiration through the Miller Abbott tube or through a tube inserted through the anus up and above the suture line. The procedure of left colectomy in one stage without prior diversion of the fecal stream is commonly used in certain countries with excellent results. Most of the techniques of left colectomy in one stage call for diversion of the fecal stream by means of a fistula.

The safety of the one stage operation is now well established. In a series of 543 colectomies performed by 15 different surgeons, the mortality rate was 10 per cent. However the operations will not enjoy such safety unless the cases are judiciously selected.

The authors report a series of 15 one stage left colectomies for cancer without death or postoperative complications. There were 3 cases in which there was no diversion of the fecal stream. In 7 cases diversion of the fecal stream was established at the time of resection and anastomosis. In the remaining 3 cases diversion was instituted prior to the colectomy.

Fig. 1. (D Allaine and Carillo-Maurtua) The temporary diversion. a, Diversion by cecostomy is sufficient when the colon is not distended. b, Proximal diversion just above the anastomosis. The proximal end of the bowel is closed on a De Pezzer catheter. It must be employed when the colon is distended at the time of operation.

Left colectomy in one stage with contemporary diversion was suggested by one of the authors in 1943. It consists of segmental resection of the left colon followed by a side-to-side anastomosis which is protected by a contemporary diversion performed proximal to the line of anastomosis. The retroperitoneal spaces are dusted with sulfonamide drugs and may or may not be drained through a contralateral lumbar incision.

The authors believe that the technique of Wangenstein should be used only in favorable cases and even then diversion of the fecal stream is advisable because the latter procedure carries only a few disadvantages and adds to the safety of the operation. Contemporary diversion of the fecal stream prevents tension on the suture line. The fistula can be easily closed as soon as feces have gone through the anastomosis unless such closure occurs spontaneously, which frequently occurs.

For the establishment of such diversion the authors at first used the colonic segment just proximal to the anastomosis. This provided excellent diversion and prevented distention of the suture line. However in later cases the simple cecostomy has been preferred because of parietal complications observed in a patient who had an inflammatory growth of the colon. At the present time diversion just proximal to the anastomosis is used only if the afferent colon seems distended at the time of the operation.

In spite of the protection assured by diversion of the fecal stream, it is imperative that the anastomosis meets all the requirements of strength, permeability and elasticity. The side-to-side anastomosis is the procedure of choice when it is from 10 to 12 cm. in length and performed with interrupted sutures. Thus it will never be exposed to the dangers of obstruction due to edema. The main advantages of this anastomosis is the length of the stoma and the assurance of an adequate blood supply. However it is not without disadvantages as it requires a great deal of tissue. Such a problem however can be

Fig. 2. The long side-to-side anastomosis with interrupted sutures. The seroserosal row has been completed, the total posterior row of sutures has been started. This figure also shows the diversion just proximal to the anastomosis below the incision in the abdominal wall. It is important to identify and safeguard the left meter.

solved relatively easily if one is careful in mobilizing the colon. The anastomosis is performed with 2 rows of sutures placed in such a manner that the knots can be tied inside of the lumen of the bowel. The so-called closed or aseptic techniques constitute a great step forward in the technique of bowel anastomosis.

Once completed the anastomosis may be exteriorized extraperitonealized, fixed to the peritoneum, drained or simply returned to its normal place in the abdomen and the abdomen closed without drainage.

Fig. 3. The operation in two stages, second method. The unbroken line is the first stage and the dotted line is the second stage.

The authors believe that if the cases are properly selected and the anastomosis is adequately performed any procedure devised to protect the peritoneum presents more disadvantages than advantages. Such preventive measures are indicated only if the strength of the anastomosis is questionable.

Drainage of the retroperitoneal spaces is a matter of controversy. The authors use drains in obese patients in which mobilization of the colon is tedious and difficult or when it is impossible to secure good hemostasis. In the average case the instillation of sulfonamide drugs is sufficient.

In a thin subject with a thin mesocolon resection of the colon is done before resection of the mesocolon. The vessels of the mesocolon are divided separately between small clamps of the Leriche type. Unfortunately such a maneuver is very difficult in obese patients with a thick mesocolon in which the vessels are not apparent. In these instances, the authors proceed in the following manner: first section of the proximal colon, then section of the mesocolon, and last, section of the distal colon. The resected segment takes the shape of an isosceles triangle, the base of which, at the colon, must measure at least 7 cm. on each side of the growth.

Section of the colon is accomplished with the electric knife after the bowel has been crushed. For the latter procedure the clamp of Goetze is preferred to the De Martel crusher which is not always as easy to put into place. The distal end of the bowel is always closed with 3 rows of size 00. chromic catgut; the proximal end is treated in a different manner depending on whether or not diversion is necessary. If diversion is decided upon the end of the bowel is closed on a De Pesser catheter and fixed to the peritoneum. If cecostomy is to be performed the proximal end is then closed in the same manner as the distal end.

After completion of the posterior seroserosal row, the bowel is opened for 10 or 12 cm. The lumen of the bowel is thoroughly cleaned with pads saturated with ether as suggested by Locene. For the insertion of the total row of sutures the authors advocate the use of linen inserted with Bergeret's needle. The sutures are placed close together and inserted in such a fashion as to have the knot inside of the lumen. The anastomosis is completed by suturing the anterior seroserosal row again with fine linen. The anastomosis is dropped into the abdomen. The rent in the mesocolon is obliterated and a sulfonamide drug is dusted into the retroperitoneal spaces.

The wall is usually closed without peritoneal drainage. Before the skin is closed a few grams of sulfonamide are deposited on the line of sutures in the fascia.

The cecum is "fistulized" and a De Pesser catheter is buried in the wall of the cecum according to Fontan's technique. The cecum is then fixed to the parietal peritoneum. In certain cases the cecostomy must precede the colectomy.

Due to the extent of the cancer or the poor condition of the patient the ideal resection is often

contraindicated. To overcome the disadvantages of an exteriorization operation a two stage procedure preceded by anastomosis has been suggested by one of the authors. There are two methods. The first consists of a colocolic anastomosis, followed by resection of the segment of bowel bearing the growth as the second operation. Unfortunately the second stage is very laborious because of the great number of adhesions around the anastomosis, the growth, and the mesocolon.

In the first stage of the second method the transverse colon is resected and a side-to-side transverse sigmoidostomy is performed distal to the growth. The second stage is easy as a rule. It consists of resection of the left end of the transverse colon and the growth with the corresponding mesocolon.

The authors have learned by experience that these two operations have different indications. The second method is feasible only when there is no obstruction. On the other hand the first method is especially indicated in cases of partial obstruction; however its value today is being questioned by the authors since a simple cecostomy followed by a one or two stage colectomy may be a better procedure.

The two stage left colectomy without exteriorization has been performed 6 times by the authors for the treatment of cancer. Both methods were used in 3 cases and no deaths occurred.

In the 2 stage operation without exteriorization the same technique and surgical principles with respect to the anastomosis are followed in the first stage as in the one stage procedure.

The anastomosis must be 10 or 12 cm. in length and two rows of interrupted sutures are necessary. The rent in the mesocolon is obliterated and the abdominal wall is closed without drainage.

Resection of the cancerous segment is done in the second stage. A period of from 2 to 3 weeks is allowed to elapse between the two stages. A transverse or a left oblique lateral incision is made according to the location of the tumor in the splenic flexure or the descending colon.

After complete mobilization of the growth, the colon is resected between the anastomosis and the tumor; the corresponding mesocolon being removed. The end of the colon is then closed, a sulfonamide is dusted in the retroperitoneal spaces, and the abdominal wall is closed without drainage.

For the same operation, the superiority of the modern statistics is explained mostly by the progress made in the preoperative and postoperative treatment. The use of penicillin and succinylsulfathiazole associated with a high protein intake is of great value. The authors state that they have as yet been unable to use several of the wonderful drugs so popular in the Anglo-Saxon countries.

The authors advocate the following preoperative measures. Ascorbic acid in daily dosage of from 300 to 500 mgm. and from 5 to 20 mgm. of vitamin B are prescribed daily until complete wound healing has taken place. Whole blood plasma, and intravenous solutions are of great value to correct de-

iciencies. No amino acid preparations are available as yet in France. A laxative is administered daily properly for from 5 to 8 days in order to keep the bowels empty.

The postoperative treatment is somewhat similar to that used for any major operation in the abdomen.

In the last part of their article the authors discuss the indications for the various operations employed in the radical treatment of cancer of the left colon except rectosigmoid cancer.

Colectomy in one stage with contemporary diversion is contemplated only if the patient is in good condition with no co-existing pathology and is under 70 years of age. For old and weak patients with co-existing lesions such a procedure is contraindicated.

The results of the preoperative treatment are of great importance in selecting the type of operation. Some patients first thought to be unsuitable for colectomy in one stage meet the operative requirements at the completion of the preoperative treatment.

The general condition of the patients may justify such an operation but certain problems must be considered and solved by the physical examination, the x-ray studies and the operative findings. The location of the growth is irrelevant but a palpable tumor must be considered with caution. Laparotomy in these cases will show the invasion and mobility of the tumor. The operation is contraindicated in the presence of subocclusive phenomena. Infection also represents a definite contraindication for colectomy in one stage. The patient must remain afebrile and have a white blood count which is within the normal limits.

As a rule, the finding of metastasis contraindicates radical surgery because the hope of curing the patient is fallacious.

When the growth is resectable and when a single and small metastasis is found a one stage colectomy should be preferred to a two stage operation should one decide to operate, because the disadvantages of an operation in stages should not be imposed on a patient whose life expectancy is limited.

As to the indications of the operation in two stages without exteriorization any patient who carries a resectable cancer of the left colon should be given the benefit of a two stage operation if he is more than 70 years of age or if he is in poor general condition. However such an operation is sometimes necessary on a relatively young patient in good general condition because of fixity of the growth in the rectum or the presence of bowel obstruction.

The operation in two stages (second method) is reserved for the nonobstructed patient. The existence of obstruction demands an emergency colectomy. Later on a one or two stage colectomy is performed.

The operations with exteriorization have very limited indications according to the authors. They should be reserved for cases with growths fixed to neighboring structures or those in which operability is questionable.

GERARD GAGNON, M.D.

Wright L. T. Freeman W. A., and Bolden J. V.: Lymphogranulomatous Strictures of the Rectum. A Résumé of 476 Cases. *Arch. Surg.* 1946 53 499.

The authors have studied a series of 476 consecutive cases of fibrous inflammatory stricture of the rectum due to lymphogranuloma venereum at the Harlem Hospital, New York, New York, during the 15 year period from 1930 to 1945.

The causative agent of the disease is a filtrable virus which can be cultivated on chick embryo mediums. Rodanische, by experiments with cross immunizations indicated that there were 7 strains of the virus and subsequently, Palmer Kinsner and Rodanische identified 5 strains in material studied by them. In the series studied here 437 patients were women 453 were Negroes. The highest incidence occurred in patients between 30 and 40 years of age.

The primary infection as noted by Fren David and Grace may take place in men by pederasty and in women by infection of the vagina or cervix and lymphatic vessels of which drain directly into the perirectal or pelvic glands.

Gerota found that the anogenitoinguinal lymphatic system communicates with the rectum by multiple anastomoses and that in the lateral wall of the rectum, in all the tunica muscularis between the latter and the fascia rectoprocta immediately above the insertion of the levator ani, there are 6 to 8 lymph glands which receive lymph from the lower portion of the rectum. These glands are now called the glands of Gerota.

Bartels and Biberstein have produced data to show that the superficial lymphatic network of the vulva goes to the superficial inguinal glands and that the abundant network of the clitoris passes to the deep inguinal nodes and a few of these directly to the external iliac and hypogastric nodes. The posterior part of the vulva has also direct lymph pathways to the anal network of glands, which drain partly into the inguinal glands, partly into the anorectal glands and partly omitting these glands, directly into the third of the vagina. The lymph vessels of the lower upper portions pass mainly to the middle and gastric glands while some pass directly to the anorectal glands. The lymph vessels of the uterus go directly to the preaortic and sacral glands. Lymph glands which leave the rectal wall above the insertion of the peritoneum flow to the mesorectal lymph glands and the glands of Gerota. Many lymph vessels lead rectally through the fascia of the rectum to the hemorrhoidal vessel. Bartels and Biberstein have also pointed out that the virus of lymphogranuloma venereum is able to produce a proliferative stimulus in the surrounding tissue. There are few anastomoses between the right and left sides and between the superficial and deep lymphatic vessels. It has been noted that chronic lymphostasis leads to a disturbance of nutrition in the affected regions. Bloom

concluded that obstruction of the lymph pathways leading to the inguinal gland causes a diversion of the lymph stream toward the rectum, and thus the infection is shunted to Gerota's glands.

Schreiner Beiner pointed out that in women there is a connection between the vaginal plexus and the hemorrhoidal plexus through the pudendal veins, so that infectious material usually passes from the vulva to the rectum.

Most authors are of the opinion that a determining factor in the production of rectal strictures is a resultant disturbance in the lymphatic flow produced by the infection.

It is the authors' opinion that lymphostasis plays an important role in the pathogenesis of rectal strictures in three ways: (1) blockage of the lymph glands and interference with adequate drainage, (2) involvement of the lymph channels themselves, due to the action of the virus, and (3) a specific scar tissue producing action of the virus. Sufficient evidence has not yet been produced to show why in some instances, the condition is progressive to the point where it threatens life itself. In other instances, why it progresses to the point where it becomes a serious clinical problem of importance but ceases to progress beyond this point and finally why in some instances it is a relatively benign chronic disease. The authors believe that these features can be explained, in the light of present knowledge, only on the basis of the action of different strains of the virus and the reaction of the particular host. The complex reactions involved between different strains of the virus and the immunity reactions of the host are facts still to be elucidated.

The stricture is usually cylindrical in shape. Its length varies from 1 to 5 cm. Usually it is located 3 to 4 cm. above the anus but it has been found at 8 and 12 cm. Ordinarily it appears as a sort of funnel with a variable sized opening at the apex of the funnel. On proctoscopic examination, ulceration may be noticed on the surface of the stricture. At the point of stricture the rectal wall is usually grayish in appearance, and rigid if the stricture is well advanced, while in the early stages it exhibits reddened granulomatous patches and often congestion and edema. Fissures and condylomas around the anus are common. Perianal fistulas are not unusual. Microscopically the muscularis undergoes degeneration and becomes replaced by scar tissue, a subacute inflammatory process, which spreads between the normal elements of the tissue, following the vascular and lymphatic systems, compressing and destroying them. Masses of purulent exudate are present, with polynuclear leucocytes, debris or epithelial cells, red cells, and clusters of bacteria. The submucosa is destroyed, and in it one finds round cell infiltration. Deeper there are areas of round cell infiltration, groups of polynuclear leucocytes, eosinophils, mast cells, and many plasma cells. Nodular masses, which are often palpable, are composed chiefly of round cells and have a center which often softens and takes on all the appearance of tuberculosis. Palpable for

mation is not unusual, and this feature is used as a basis for diagnosis. In short, the appearance is that of a chronic granuloma of the rectum.

The pathologic changes of the disease, aside from the gross evidence of stricture in the rectum, consist in the early stages of a reddened friable mucosa which bleeds easily on touch or proctoscopic examination and is due to thickening and ulceration. The thickening involves all layers of the rectal wall mucosa, submucosa, and tunica. Often the three layers are fused into a hard and thickened, dense mass, in which the normal histology of the rectum is lost. The scar tissue extends deeply into the adjacent perirectal tissues, and if fistulous formation is present the scar tissue extends along the tract, or tracts, to the external surface of the body. The usual site of the fistulas is below the stricture, although it has been demonstrated that they may occur above it. Proximal to the stricture there is ulceration and dilatation of the rectum or sigmoid in proportion to the degree of stenosis, with superimposed, mixed secondary infection. The obstruction to the fecal outflow plus the secondary infection is the cause of many of the secondary symptoms presented by the patients, as low grade fever, constipation, anemia, weakness, dehydration and malnutrition.

The diagnosis in cases of pure uncomplicated strictures of the rectum is made by the examining finger. External manifestations of the disease, as elephantiasis of the vulva, anal tags, fistulas, cockscomb tumors, or papillomatous tumors around the anus which are obviously of a benign nature, demand in all cases a rectal examination. In most cases examination shows the rectal wall to be thickened and narrowed. The lumen may admit the tip of the index finger or there may be almost complete occlusion, which will barely permit the passage of a urethral catheter. The diagnosis may be confirmed by proctoscopic examination if an anal stricture does not preclude the use of the instrument. The Frei test was used in this series of patients and was positive in 77 per cent. Although it is an important adjunct in the diagnosis of the disease it is not absolutely specific, and negative reactions occur in a sufficient number of cases so that absolute reliance cannot be placed in the test. Some negative reactions are due to faulty technique because positive reactions have been obtained on retesting. The Frei test should be done in all cases of suspected strictures and, when positive, is a most important confirmatory diagnostic aid. If negative, it is important to repeat the test with potent antigen and scrupulously careful technique. The cultivation of the virus from the rectal mucosa obtained from the site of the stricture makes the diagnosis absolute. Hyperproteinemia with a definite increase in the serum globulins in excess of 3.5 per cent is a suggestive diagnostic sign of lymphogranuloma venereum. The reversal of the albumin-globulin ratio in early and late cases, which persists as long as active infection remains, has been stressed. The sedimentation rate has not been of diagnostic help.

Biopsy should be used in two ways (1) to rule out the presence of a coexisting carcinoma which occurs as a superimposed factor in a significant number of patients, and (2) to isolate the virus when laboratory facilities make this possible. Except for the finding of a low grade anemia and an increased sedimentation rate in those with secondary infection the other laboratory findings are, in general, normal. Roentgenological examination by barium enema will demonstrate the stricture as to location and length. A disadvantage of this technique is that the barium may become inspissated and aggravate the clinical condition. To obviate this a balloon filled with sodium iodide has been passed through low strictures and the films taken.

The signs and symptoms obviously vary according to the location and degree of the stricture.

The differential diagnosis of lymphogranuloma venereum considers intestinal tuberculosis, ulcerative colitis, carcinoma of the rectum, diverticulitis, chemical strictures and rarely in this country strictures due to parasites or amebic ulcers.

As to the prognosis of the disease rectal strictures are the most serious clinical condition that results. Many persons in whom strictures of the rectum develop live to an extremely old age. In other instances, the stenosis not only causes disability and prolonged morbidity but is the real cause of death. The disease is progressive at times, often it is apparently static, and in the present light of our knowledge it is impossible for anyone to separate with accuracy the conditions that will progress and those that will not. Tuberculosis develops as a death producing factor in many cases pneumonia is a serious factor in other instances. Acute and chronic intestinal obstruction develops not infrequently. Rectal strictures are a common cause of death, but often the death producing factor is not considered to be the stricture because of other complications.

Treatment consists in the use of drugs, biologic methods and surgery.

Of the drugs used none have been impressive in their results. However the use of the sulfonamide drugs in the prestricture stage of the disease may in some instances prevent further progress of the condition and in this way stop the formation of strictures, but this evidence is not conclusive. Sulfathiazole, sulfanilyl sulfanilate, succinylsulfathiazole, and phtalylsulfathiazole will clear up much of the super imposed secondary infection and thus improve the condition of the patient.

Biologic methods consist in the use of antigens, estrogens, irradiation, diathermy and solid carbon dioxide.

Frei antigen is still recommended by some clinicians. In this series it has proved valueless, having been used in over 200 cases without effect.

Estrogens have been used on the basis that pregnancy seemed to help rectal strictures by causing a softening of the genital, pelvic, and perineal tissues during childbirth. This has been refuted by observation of other series of patients.

Irradiation is mentioned because patients have been seen who have received radium therapy. From the results observed there was no lessening of the progress of the condition.

There are many reports of the successful use of diathermy in this disease. It has been used in the present series of patients with totally unsatisfactory results.

Solid carbon dioxide was used for a long time and discarded because it served no useful purpose.

Some conditions do not progress rapidly and are not serious, while others progress rapidly in spite of all forms of therapy except early excision. Colostomy helps many patients by (1) lessening secondary infection, and (2) overcoming the toxic effects of chronic obstruction of the bowel. Surgical treatment alone is of value once a fibrous stricture of any considerable extent has developed. Warten's obliteration of the cul-de-sac operation offers the possibility of lessening the complications that are inherent in colostomies, namely anterior grade and retrograde herniation. It cannot prevent stenosis of the colostomy opening which occurs in many instances. Pauchet's excision operation, or a modification thereof at this time offers the best method of cure for strictures low in the rectum. This does not exclude the sacroperineal excision operation of Hartmann. These operations are of such magnitude that they should be performed only by experienced surgeons. When the disease involves the entire rectum and the rectosigmoid area, abdominoperineal extirpation is indicated if the patient a clinical condition does not improve after colostomy. In the rare cases in which the descending colon is involved, a permanent artificial anus in the transverse colon should be made.

Much further study is needed to complete our knowledge and understanding of this subject.

EDWIN W. PARSANELLI, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Pignatelli, G.: Research on Fibrinogen in Surgical Affections of the Biliary Tract (*La ricerca del fibrinogeno nelle affezioni chirurgiche delle vie biliari*) *Gior Ital chir* 1947 3 130.

A study was made of 18 patients with affections of the biliary system in which the blood fibrinogen and the glycemie curve as a control were used as an index of liver function.

Fasting blood was taken the day before surgery and repeated 15 days and 2 to 3 months later for the determination of the glycemie curve and the blood fibrinogen. The method of Hagedorn and Jensen was adopted for determination of the glycemie curve while the technique originated by Whipple and Foster was used for the blood fibrinogen.

The author's observations were as follows (1) chronic cholecystitis of long duration presented a noted diminution of fibrinogen accompanied by an alteration of the glycemie curve, indicating a lesion of liver parenchyma as a result of the chronic inflam-

matory process however 15 days postoperatively the blood fibrinogen and the glycemic curve returned to normal. (2) In one case of jaundice resulting from a tumor of the head of the pancreas the fibrinogen was diminished to nearly half the normal parallel with a great alteration in the glycemic curve. (3) In 2 instances of postoperative biliary fistula the fibrinogen was diminished, but returned to normal after closure of the fistula. (4) In cholelithiasis without jaundice, there was no appreciable alteration in the blood fibrinogen or the glycemic curve.

The author's studies show that fibrinogen represents a good index of liver function in those cases with an inflammatory process of long duration and a return to normal of the blood fibrinogen and the glycemic curve after the beneficial effect of surgical intervention. However, in cases of fatty degeneration of the liver parenchyma, a normal or increased value of blood fibrinogen may be found.

ARTHUR F. COPIOLA, M.D.

Cattell, R. B.: Strictures of the Biliary Ducts. *J. Am. M. Ass.* 1947 34 35

The operative intervention to restore normal bile flow into the intestinal tract in benign strictures of the biliary ducts presents many technical problems which tax the ingenuity of the surgeon.

A short review of the literature on this subject is presented.

The incidence of benign stricture is difficult to determine accurately. At the Lahey clinic, in Boston, only 1 stricture in 5,000 operations on the gall bladder was encountered. The ratio was to 50 when compared with gall bladder operations during a 4 year period. The ratio of benign stricture to obstruction of the biliary ducts due to cancer is 1 to 5.

A series of 123 patients with benign stricture of the biliary ducts operated on at the Lahey Clinic prior to January 1, 1945 was used as the basis of this report. Eighty per cent of the patients were women, the youngest was 21, the oldest 75 years, and 30 per cent were less than 40 years of age.

Strictures were due to operative injury in 99 cases (80%). The author believes that these certainly should be preventable. They may occur as the result of poor anesthesia, uncontrolled hemorrhage from the cystic artery, inadequate exposure and light, failure to recognize the anatomic variations of entrance of the cystic duct into the common duct, or distorted anatomy due to a badly inflamed or contracted gall bladder. In order to avoid these accidents the surgeon should completely demonstrate all anatomy before attempting the division of any structures. Although cholecystectomy is the operation of choice for a patient with gall stones, cholecystostomy is indicated if the surgeon believes that satisfactory dissection is impossible because of the risk of injury to the duct.

Hemorrhage from the cystic artery during operation with blind attempts at control, frequently results in injury to the common hepatic duct. This

can be avoided by pressure on the hepatic artery, compressing it between a finger in the foramen of Winslow and the thumb anteriorly on the gastrohepatic omentum until the cystic artery stump can be secured.

Explorations of the common bile ducts during operations on the gall bladder have not contributed to stricture formation.

The site of stricture was the common bile duct, or both hepatic ducts in 49 patients. The lower end of the common duct was injured in a localized area in 32 patients. Large portions of the extrahepatic ducts were found to be excised in 18 cases. Injuries at the site of cystic duct entrance were due to interference with the lumen of the duct because of too close ligation of the cystic duct or removal of a portion of the duct at this point.

In 11 patients, long-standing inflammation of the ducts resulted in stricture. Earlier operative interference in these long-standing cases of biliary disease might have prevented strictures. Fibrosis and narrowing of the ampulla of Vater was the cause of stricture in 9 patients—a cause which is frequently overlooked unless it is determined by the passage of graduated probes or transnodal exploration. Adhesions and external trauma were infrequent causes of strictures.

The time for effecting a repair is very important. Repair of operative injuries is best accomplished at the time of the original operation. If the injury is discovered during the postoperative period, it is better to wait until the inflammation and edema subside when strictures are pliable. Many failures are the result of too early interference. If there is an external biliary fistula, operation should be delayed at least 3 months. If obstructive jaundice persists, operation should be carried out in from 4 to 6 weeks. Every attempt at repair if unsuccessful, makes later procedures more hazardous.

In the presence of an external biliary fistula, a short period of preoperative preparation is necessary. In severe obstructive jaundice 2 or 3 weeks' preparation may be necessary to get the patient in the best operative condition. A high caloric, high protein, low fat diet, augmented by vitamins B, C, and K, is recommended. Intravenous dextrose, amino acid mixtures, and blood transfusions are given preoperatively if indicated.

The author prefers fractional spinal anesthesia and uses tetracaine hydrochloride weighted with dextrose. If general anesthesia is required, intratracheal cyclopropane is preferred.

A total of 344 operative procedures on 123 patients were carried out, 280 of the operations having been done prior to the patient's admission to the Lahey Clinic. The serious nature of duct strictures is shown by the extent and number of surgical procedures, the severe hepatic damage and the long period of disability with economic loss.

All operative repairs consisted of (1) plastic procedures with end-to-end suture for restoration of continuity and preservation of the sphincter of Oddi,

or (3) suturing of the proximal portion of the duct to some portion of the gastrointestinal tract (stomach duodenum or jejunum)

The principles of treatment for a successful repair are given in detail. Whenever possible the author employs a procedure which preserves the sphincteric action at the ampulla. The difficulties involved in locating the lower end of the duct can be overcome with increasing experience. Adequate portions of the distal duct can be obtained; the duodenum is mobilized drawn forward and turned to the left. The anterior division of the superior duodenal artery can be sectioned and the pancreas split so that the intra-pancreatic portion of the common duct may be identified and dissected free for 2.5 to 5 cm. the mobility of this portion of duct enables its approximation to a short proximal stump without tension.

The author divides his series in two groups which differ chiefly in that there is a great increase in end-to-end sutures in the latter group. The transplantation of fistulas has been discontinued. In the author's last 38 cases (not included in this series) anastomosis of the duct to the gastrointestinal tract was not done except in rare cases.

The type of material over which the anastomosis is made is unimportant since all will pass. Rubber T tubes, vitallium or bouncing clay tubes have been used successfully. The tubes should have as large a lumen as possible to avoid plugging. When a T tube is used it is left in place from 6 to 12 months.

Anastomosis of the duct to the gastrointestinal tract was carried out in 28 cases. Hepaticojejunos-tomy is the procedure of choice. The author uses a long loop of jejunum antecolic with an enteroenterostomy or the Y-loop or Roux principle.

Postoperative care is similar to that following any serious abdominal operation. Vitamin K is given parenterally for 1 week. Blood transfusions and infusions of dextrose and amino acids are given when indicated. The drainage of bile from the wound usually ends in 2 weeks. A choleagogue is used for several months if a tube is left in the duct system. If a T tube is used it is irrigated with saline twice daily after the first week.

In the first group of 80 patients there were 14 deaths, and in the second group of 43 cases there were 3 deaths. The reduced mortality is attributed to improved pre- and postoperative care, the use of vitamin K, and increasing operative experience.

The longer the cases are followed the greater the recurrence of symptoms. A follow up of 21 patients with anastomosis of the duct to the gastrointestinal tract showed completely satisfactory results in 12 patients, 4 were improved, 9 were unimproved and of these 8 were reoperated upon. There were 4 deaths in this group.

Of the 30 patients with repair by vitallium tube, in 7 the duct was anastomosed to the intestine and in 23 the duct was reunited over the tube. Satisfactory results were obtained in 25 cases. There were 3 deaths; it was necessary to remove the tube in 2 cases, and the tube was passed in 2 cases.

The most satisfactory results followed end-to-end repair of the duct or plastic repair of the duct over a T tube. Recurrence of stricture may take place at any time and require reoperation.

ROBERT R. BROWNE, M.D.

Stajano, C.: Congenital Dilatation of the Hepatic Duct and Main Duct (Megacholedochus) (Dilatación congénita del hepato-cóldoco-megacóldoco) *Boi Soc cir Uruguay* 1946 17 261

Stajano reports a very interesting case of congenital dilatation of the main duct. The patient was a 25 year old pregnant woman who had mild gastrointestinal and urticarial symptoms during the first months of pregnancy but in the ninth month she had frequent vomiting and pain in the dorsal column. She delivered a normal child. Thirteen days after delivery she had marked distention in the right upper quadrant of the abdomen. On palpation a cystlike mass of the size of the head of a fetus was felt which was thought to be a hydatid cyst of the liver. An eosinophilia of 5 per cent was found and the Cassini test was slightly positive.

The patient was followed up in the hospital for nearly 6 weeks, during which time the mass increased in size and in tenderness. The pain radiated to the epigastrium and the posterior base of the thorax. At

Fig. 1 (Stajano) Cholangiography of an enormously large dilated congenital main duct.

Fig. 2. (Stajano) Appearance of the successfully resected congenital main duct which was anastomosed to the stomach and duodenum in tubelike form.

operation an enormous dilatation of the main duct which contained nearly 600 c.c. of black bile was found this was drained. In a second operation a large portion of the main duct was resected, and a tubelike structure was made and anastomosed to the stomach and duodenum (Fig. 2). The patient made an uneventful recovery and 3 months later was symptomless and had gained 8 pounds in weight.

WILLIAM E. RIZZETTA, M.D.

Hicken N. F. White, L. B. and Corry Q. B.: Incomplete Removal of the Cystic Duct as a Factor in Producing Postcholecystectomy Complications. *Surgery* 94:7 399.

Whenever a gall bladder becomes diseased the pathological process invariably spreads to the cystic duct. Therefore the authors conclude that the entire cystic duct should be removed with the diseased gall bladder. The fact that this is not invariably done and secondary operations become necessary is attested to by numerous case reports in the literature. Failure to appreciate the anatomic anomalies of the cystic duct is often responsible for failure to remove it. However any abnormality of the cystic duct can be detected accurately by taking cholangiograms during the operation, a procedure which the authors advocate in all doubtful cases.

The residual cystic duct may become dilated and form an excellent receptacle for bile but as the duct lacks the contractile properties of the gall bladder it cannot evacuate its contents. Stasis infection and stone formation result. Or the cystic duct may harbor an undetected stone at the time of the initial operation, which later causes serious symptoms. And finally adhesions to the residual cystic duct may cause serious kinking of the common duct with resultant symptoms of obstruction. The authors

present case reports illustrating each of these mechanisms.

F. J. LUTHEMAN, JR., M.D.

Senty P., and Duroux, P. E.: Removal of the Ampulla of Vater in the Course of Gastroduodenectomy for the Curative Treatment of Ulcer (La déssection de l'ampoule de Vater au cours de la gastroduodénectomie pour ulcère. Traitement curatif). *Lyon chir* 1947 42 13.

Injury to the common bile duct and the pancreatic duct of Winsung is a real hazard in the course of gastroduodenectomy for ulcer particularly for ulcers of the posterior wall which perforate into the pancreas. Wounds of the terminal portions of these ducts may easily be overlooked at the time of operation and readily prove fatal. If they are recognized at the time of injury their immediate repair is not difficult.

Attempts to repair such injury may be in the nature of anatomical restoration, a biliary side tracking procedure, or fistula anastomosis. Anatomical restoration can be done only when the ducts are injured several millimeters above the ampulla of Vater and the ampulla is left intact, and is accomplished by anastomosis of the cut ends of the ducts over small catheters.

Biliary side tracking procedures such as cholecystoduodenostomy with ligation of the common bile duct provide for the flow of bile but do not provide for the flow of pancreatic juice. On the other hand, pancreatic fistula anastomosis is a practical method of restoring the pancreatic duct but does not provide for the flow of bile.

The authors have devised the following procedure to accomplish restoration of both ducts. Once the injury to the ducts is recognized, the duodenum is sectioned below the ulcer bearing area while the anterior wall is left as long as possible, and the cut end of the duodenum is drawn down over the base of the pancreas and the ampullary portion in such a fashion that the severed canals empty into the intestinal lumen. The duodenal wall is anastomosed to the end of the pancreas with three layers of sutures. Good suspension of the afferent limb of the gastrojejunostomy aids in the prevention of regurgitation and a temporary cholecystostomy allows decompression of the biliary tree.

The advantages of this procedure are that it controls both the pancreatic and biliary duct systems, establishes a normal physiologic pathway for the flow of biliary and pancreatic juices, avoids cholecystoduodenostomy and does not prolong the operating time.

Four patients have been treated by this method and have done well for periods of 5 years, 4 years, 3 years, and 6 months. EDWARD W. GIBBS, M.D.

Wirts, C. W., Jr., and Snape W. J.: Disseminated Calcification of the Pancreas. Subacute and Chronic Pancreatitis. *Am J Med Sc.* 94:7 13 390.

The incidence of pancreatic lithiasis is not high aggregate figures showed only 31 cases among

117,031 routine autopsies. The authors wish to draw attention to a special form of pancreatic lithiasis known as disseminated calcification of the pancreas. This disease is thought to be distinct from the usual form of pancreatic lithiasis.

The cause of this disease is not known, but it is generally believed to result from repeated attacks of acute or subacute pancreatitis occurring in adult life. Pathologically the pancreas shows the presence of extensive interlobular and intralobular fibrosis, with considerable mononuclear cell infiltration. The parenchyma of the gland is largely replaced by this fibrosis. The entire ductal system, including the smallest ducts, contains minute calculi.

The outstanding symptom of disseminated calcification of the pancreas is abdominal pain, usually existing over a period of months or years. The pain is usually gnawing and boring in character and is present in the epigastrium with radiation to the back. Particularly severe attacks of pain may arise following an excessive intake of alcohol.

Steatorrhea and creatorrhea are present in about 25 per cent of the cases. When they persist for any length of time, weakness and weight loss may be pronounced. Transient jaundice may occur. Diabetes is rarely present (2 of the 24 reported cases).

The most significant laboratory finding is a diminished pancreatic secretion following the intravenous injection of secretin. Steatorrhea and creatorrhea may be present. The typical roentgen ray picture shows a diffuse stippled calcification involving the entire pancreas.

Relief of the acute symptoms usually requires the administration of morphine. If true pancreatic insufficiency is present, a low fat, high caloric diet, with vitamin therapy and large doses of pancreatin are beneficial. Partial or total pancreatectomy may be necessary for intolerable pain. One of the greatest benefits occurring from the proper recognition of this disease is that it may prevent the needless removal of a gall bladder, appendix or kidney. Two case histories are given. F. J. LEEMAN, JR., M.D.

GYNECOLOGY

UTERUS

Falconer B.: Investigations on the Uterine Mucosa. Biopsy Material, Its Treatment and Evaluation. *Acta obst. gyn. scand.*, 946, 26 453.

The author points out changes which may occur in biopsy material as a result of preparation and calls attention to some peculiarities in the microscopic picture. He states that the technique by which the biopsy material was obtained should be known to the pathologist since there is a difference both in quantity and in the amount of injury to the mucosa, depending upon how the specimen was obtained. The use of the suction curette may remove only small bits of mucosa and its removal may be more superficial than by curettage and hence less reliable for interpretation of abnormal changes.

The changes produced in biopsy material by curettage are the following (1) fresh hemorrhage due to breaking down blood vessels with the instrument (2) signs of invagination in the glands, except in the basals where it is normal, and (3) certain necrotic changes which may in part be due to the method of fixation.

The preparation of the material is important since it is desirable to fix the tissues in a manner which will demonstrate the changes actually present at the time of removal both the epithelial and the stromal elements should be preserved. An ideal method for showing all the functions would be to fix the tissues in absolute alcohol, embed in paraffin, and stain with (1) Best's carmalum, (2) hematoxylin eosin, (3) van Gieson stain and (4) toluidine blue. The ideal stain for secretion should differentiate between secretory products ready to be expelled and those in the early stages of development.

The cyclic variations in the epithelial elements include the ordinarily recognized changes occurring during the menstrual cycle and, in addition, certain changes in individual cells have been recognized for instance the nucleus in a cell bulging with secretion may be displaced toward the lumen rather than the periphery of the gland—a condition which the author denotes as "secretion retention." Other cells are large with pale nuclei and apparently empty cell bodies which are jammed in between seemingly normal cells.

The stromal constituent should undergo cyclic alteration with the epithelial elements however in some instances the author observed no pregravid alteration of the stroma, although there was noted a well developed secretory glandular activity and in other cases the reverse was true. This is believed to be due to abnormal stimulation.

The author concludes that in every case the whole picture of what is happening to the endometrium cannot be evaluated even with good biopsy material.

J ROBERT WILLSON M.D.

Falconer B.: Investigations on the Uterine Mucosa. The Occurrence and Significance of Ecrotic and Cystic Glands in the Uterine Mucosa. *Acta obst. gyn. scand.* 1946, 26 475.

The author reviews the literature on abnormalities of the endometrium and concludes that occasional cystic or enlarged glands are merely physiologic variations. Enlarged and cystic glands are known to occur in association with endometrial hyperplasia, cystic glandular hyperplasia, endometritis atrophy myomas and in retrogressive hyperplasia.

Twenty cases of cystic enlargement of endometrial glands found in endometrial biopsy material from women still in the reproductive phase of life are discussed. The cases are divided into two groups of 10 each, in the first of which there was a known pathological condition as an explanation for the change. Included were 2 patients with myomas, 4 with cystic glandular hyperplasia, and 4 with hormonal deficiency. None of the second group could be classified as to the causes of cystic formation, but 5 patients were sterile and 5 had suffered habitual abortion. The author concluded that the presence of enlarged or cystic glands should suggest ovarian deficiency.

J ROBERT WILLSON M.D.

Falconer B.: Investigations on the Uterine Mucosa. On the Early Diagnosis of Metropathia Hemorrhagica. *Acta obst. gyn. scand.* 946, 26 535.

In an attempt to make a diagnosis of metropathia hemorrhagica cystica early in its course, the author suggests several changes in the endometrial glands and the stroma which occur with this condition.

The alterations in the glands are an abnormal increase in number and groups of closely packed glands which may show signs of invagination or which may be dilated and cystic. The cells may be cylindrical and contain elongated nuclei which are rich in chromatin. The stromal changes are areas of cellular hyperplasia in which the cells are spindle shaped and contain large numbers of connective tissue fibrils the blood and lymph vessels are dilated.

Six cases in which several endometrial biopsies were obtained are presented. In 4 of these the microscopic changes were noted at a time when there was no abnormal bleeding which however subsequently appeared.

J ROBERT WILLSON M.D.

Goerriero, W. F. Jennett, R., and Mantooth, W. B.: Infectious Granulomatous Lesions of the Cervix. *J Am M Ass.* 947 33 83.

The authors note that the group of infectious granulomas of the cervix include lesions resulting from tuberculosis, granuloma inguinale, syphilis, and chancre. Their importance depends on their morphological resemblance to carcinoma as seen at speculum

examination and in addition the symptoms of the granulomatous cervical lesions are basically those of carcinoma. Minor deviations of this are pointed out in the clinical course, therapy, psychologic effect on the patient, and the prognosis are vastly different from those in carcinoma.

Over a period of 3 years the authors observed 123 patients on whom biopsy of the cervix was done. Microscopic examination of the tissues revealed carcinoma in 34 (10.4%) cervicitis in 79 (64.6%) cervical polyp in 3 (2.5%), leucoplakia in 3 (2.5%), squamous metaplasia in 2 (1.6%), granuloma inguinale in 3 (2.5%), tuberculosis in 2 (1.6%), tertiary syphilis in 1 (0.8%) and chancroid in 1 (0.8%). In addition, 26 cases of primary and secondary syphilis, and 1 case of chancroid were found in the group of patients studied.

A discussion of tuberculosis of the cervix is presented. Clinically the diagnosis is seldom made although one must be suspicious of all granulomatous lesions of the cervix in patients with tuberculosis elsewhere. The treatment may be curative or palliative according to the parity and age of the patient, the location and extent of the lesion, and the number of distant foci. The operation may consist of cervical amputation or total hysterectomy.

The cervix is now recognized as a primary or secondary site of granuloma inguinale. When lesions are found in other locations than in the inguinal region it has been suggested that the entity be called "granuloma venereum." To avoid further confusion the authors suggest the term "granuloma venereum cervicitis."

Like tuberculosis, granuloma venereum cervicitis undoubtedly will be found, with correct diagnosis, to be a relatively common lesion particularly in the negro. The specific etiologic agent is a micro-organism the Donovan body which is probably a protozoan, has never been cultured, and is pathogenic only for man. The final diagnosis depends on a demonstration of the Donovan body in smears, scrapings or a biopsy specimen.

Therapy is general, local, and specific. General measures include adequate diet, vitamins and penicillin and sulfonamide compounds given parenterally. Local therapy in the form of sulfonamide jellies or sulfonamide powder is frequently of benefit. Specific therapy by the administration of one of the antimony compounds over a period of 6 months is advised.

This disease deserves special mention when it affects the pregnant patient. The therapeutic response is poor, infection is common and large growths may cause dystocia, hemorrhage and cervical and uterine tears. In some cases delivery by elective cesarean section with or without hysterectomy may be indicated.

Until recently syphilitic lesions of the cervix have been regarded as uncommon. In a large and carefully examined series of patients Davies reported an incidence of 44 per cent. Syphilis of the cervix may be primary, secondary or tertiary. The primary

stage is recognized by the chancre. The secondary stage appears either as an erosion, macule, papule, or ulcer. The tertiary lesion is an ulcerative or proliferative gumma and is the type most commonly confused with carcinoma.

The diagnosis of primary and secondary lesions depends on the finding of the *Spirochaeta pallida* by dark field examination, since serologic tests are not always positive until 3 weeks after the initial infection. The tertiary lesion is diagnosed by biopsy and positive serologic tests. Recognized antisyphilitic therapy is advocated for all syphilitic lesions of the cervix.

Chancroid of the external female genitalia is common but this type of cervical infection is rare. Chancroid or *ulcus molle cutis* is a highly infectious localized lesion caused by inoculation with the *Haemophilus* of Dancery, a gram-negative bacillus appearing singly or in short chains. Diagnosis is made by smear culture, Ito-Reensterna skin test and biopsy. The treatment consists of the administration of sulfathiazole parenterally and locally for from 7 to 10 days.

In conclusion, the authors note that infectious granulomatous lesions of the cervix are more common than has previously been suspected. The improvement of diagnostic facilities has made specific diagnosis of these lesions possible. When a clinical diagnosis of carcinoma of the cervix is not substantiated by microscopic examination, one of the granulomatous lesions should be suspected. The importance of specific diagnosis rests in the fact that the clinical course, therapy, psychologic effect on the patient, and the prognosis are vastly different from those for carcinoma. HAZARD F. THURSTON, M.D.

ADNEAL AND PERIUTERINE CONDITIONS

Cirio Malbrán Miguel Angeli: The Estrogenic Value of the Remaining Ovary (Valor estrogenico del ovario restante). *Obst. Gyn. Int. Amer.* 1946 4: 873.

In his study of the estrogenic power of the ovaries the author employed 44 white adult rats. First, the tubes and the uterus were removed then the remaining ovaries were implanted into other castrated rats. The function of the implanted organs was studied by examining vaginal smears of the recipient

Immediately following hysterosalpingectomy there is usually a hyperfunction of the ovaries followed by a stage of hypofunction. As a rule, the ovaries in the author's experiments were removed 160 to 180 days after hysterosalpingectomy to avoid the aforementioned fluctuations of ovarian function.

The experiments showed that the estrogenic power of ovaries remaining after removal of the tubes and the uterus is only about half as strong as that of control animals. Cyclic variations may be observed in ovarian tissue of various weight served to determine the minimum weight capable of induction of estrus in the recipient animals. Histologic studies of implant

ed ovaries disclosed the presence of normal ovarian tissue in cases in which estrus was produced. Failure of estrus to appear in the recipient coincided with involution of the implanted ovary which showed signs of atresia, hyperplasia of interstitial tissues, sclerotic changes, etc. The estrogenic effect of implanted ovaries depends on the functional condition of the ovarian tissue at the time of implantation. If the ovaries are removed during the premenstrual phase, estrus is more easily produced than in cases in which the ovaries are removed during the intermenstrual period.

All these results pertain to ovaries removed a long time after hysteroligectomy and the author stresses the fact that entirely different results may be obtained if the ovaries are removed shortly after excision of the uterus and the tubes. In all experiments, the ovaries were implanted subcutaneously in the dorsal region. JOSEPH K. NARAY, M.D.

Meleiro de Sousa, H.: Benign Tumors of the Ovary with Ascites and Hydrothorax—Meigs Syndrome (Tumores benignos do ovário com ascite hidrothorax. Síndrome de Meigs) *Rev. cli. (est. med.)*, 947, 7.

A 26 year old woman developed pain in the left lower quadrant of her abdomen accompanied by vomiting 5 months prior to admission to the hospital. Menstruation continued to be normal but nausea and vomiting recurred at frequent intervals, the abdomen continued to increase in size and the patient was losing weight.

The physical examination revealed a tumor in the left lower quadrant of the abdomen. It had a smooth surface and was mobile and slightly painful to touch. Ascites and right hydrothorax were also detected on clinical and roentgenographic examinations.

A clinical diagnosis of fibroma of the left ovary with pleural and peritoneal effusions was made and an operation was performed under spinal anesthesia. The tumor with the corresponding tube was removed and about 8 liters of yellowish fluid were aspirated from the peritoneal cavity. The fluid contained 13 per cent albumin and numerous lymphocytes. The Gram and Ziehl stain tests were negative. The tumor was surrounded by a fibrous capsule. The histologic examination established the diagnosis of pseudomucinous cystadenoma, partially papilliferous.

The patient made an uneventful recovery and on re-examination 2 years after the operation showed a gain in weight of 14 kgm.

Various factors have been accused of producing pleural and peritoneal effusions in such cases: (1) hypoproteinemia, (2) congenital communications between the pleura and peritoneum, (3) asymptomatic cardiopathy capable of sustaining circulation under normal circumstances but leading to decompensation when alterations of the pelvic circulation are present, (4) mechanical obstruction of the reflux of the venous blood to the thorax, and (5) the passage of peritoneal fluid to the pleural cavity through the transdiaphragmatic lymphatic system.

The author favors the theory of the origin of the fluid as the tumor itself. The lymphatic paths probably carry the fluid from the peritoneum to the pleural cavity. JOSEPH K. NARAY, M.D.

MISCELLANEOUS

Decker, A.: Posterior Colpotomy for the Diagnosis of Pelvic Diseases. *Am. J. Surg.* 1947 73 313.

The author notes that the vaginal route for the removal of pelvic organs and for the diagnosis of pelvic diseases has been little used in the past few decades. Prior to the advent of modern abdominal surgery, however, many pelvic surgeons considered this the approach of choice for the removal of the uterus and its appendages. Except for hysterectomy in selected cases and the rare removal of a tube in ectopic pregnancy, posterior colpotomy for pelvic surgery is now rarely employed. The literature of recent years dealing with posterior colpotomy is reviewed.

The author states that the purpose of this report is threefold. It is intended to emphasize the safety, simplicity and reliability of cul-de-sac puncture when it is performed in the knee chest position. Moreover, some of the details gained by experience thus far are related. The value of endoscopic visualization is demonstrated by case reports.

The technique for endoscopic visualization of the pelvic organs is presented in detail. Puncture of the posterior vaginal wall into the pelvic peritoneal cavity by means of a needle or trocar has been employed more than 400 times, in most instances for the purpose of endoscopic visualization of the pelvic viscera.

The cases selected for this observation presented clinical evidence before examination that varied from a normal pelvis or minimal amount of pelvic disease to large palpable tumor masses. Some were examined in the presence of extensive pathologic processes to determine the limitations of the diagnoses, which were sessile fibroma, right salpingitis, and endometriosis of the uterus, respectively.

The author is of the opinion that cul-de-sac puncture for diagnostic purposes is best employed in the knee chest position. When combined with endoscopy it is a useful adjunct to the present methods of diagnosis in obscure pelvic diseases. Cul-de-sac puncture cannot be performed through an intact hymen or when disease or atrophic conditions make the introitus and vagina inadequate. It should not be employed in the presence of acute vaginal infection or when the cul-de-sac is filled with a fixed mass that does not move out of the pouch when the patient assumes the knee chest position.

HENRY F. THURSTON, M.D.

Ercole, R.: Diverticula of the Female Urethra. Four Personal Observations (Diverticoli della uretra femminile. A proposito di 4 osservazioni personali) *Rev. argent. urol.* 945, 14 32.

Urethral diverticula occur with much greater frequency in men than in women because the course of

the urethra and the proximity of the prostatic gland in men facilitate the development of suppurative processes. In many instances diverticula in women are overlooked because urethrocystoscopy does not constitute a part of the routine examination. Therefore small diverticula may easily escape detection.

Diverticula in women may be divided into two groups: the congenital and the acquired. Those belonging to the first group may develop from Gaertner's duct, paraurethral ducts, residues of the Wolffian duct, and from vaginal cysts. Acquired diverticula usually are the result of an infection or trauma. Suppuration of a urethral gland which preserved its communication with the urethra may be responsible for the formation of a diverticulum. Instrumentation of the urethra or the passage of a stone may lay the basis for the formation of a diverticulum.

Urethral diverticula may be true or false. All layers of the urethra participate in the formation of a true diverticulum.

The most frequent symptoms of a diverticulum are pain, increased frequency and burning on urination. As a rule, an involuntary loss of a small amount of urine occupying the diverticulum follows voluntary micturition. Occasionally, as was the case in 1 of the author's patients, incontinence of urine may be present. Pressure on the anterior vaginal wall usually causes an escape of a small amount of purulent urine. Roentgenography of the urethra may reveal a diverticulum. Urethrocystoscopy with MacCarthy's panendoscope usually reveals the diverticulum.

The radical treatment consists of the extirpation of the diverticulum through an incision through the anterior vaginal wall. The defect in the urethra is closed with 3 interrupted catgut sutures and the vesicovaginal septum is closed as a separate layer. A retention catheter is introduced after the operation. Occasionally a complication in the form of a urethrovaginal fistula may develop shortly after the operation.

The author reports 4 cases of diverticulum. In 1 of them a calculus was found.

JOSEPH K. NARAT, M.D.

Sjbrall, A.: The Influence of Estrogen upon the Healing of Vaginal Wounds in Rats. *Acta obst. gynec. scand.* 1947 27: 1.

Previous experiments have demonstrated the beneficial effect of estrogenic preparations upon the healing of experimental skin wounds. This effect should be more marked in wounds of the female genital tract in which estrogen has been shown to induce hyperemia and epithelial proliferation.

The healing of experimental vaginal wounds in spayed female rats seems to be promoted by treatment with estrogen. Of 17 animals treated with subcutaneous injections of estradiol benzoate, 15 were healed in 5 days, whereas of 19 controls only 6 were healed during the same period.

These experiments tend to confirm the clinical usage of estrogen prior to operation for prolapse in elderly women.

GRACE BLONICK, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Putignano, C.: Repeated Ectopic Pregnancies (Sulla gravidanza ectopica ripetuta). *Riv. ostet. gine.* 946, 1946.

The author reviews 27 cases of repeated ectopic pregnancies encountered in the Clinic of Obstetrics and Gynecology of the University of Bari in the period from 1925 to 1944. The ages of the patients ranged from 21 to 40 years, the highest incidence occurring among those between 31 and 35 years of age. Multiparous subjects represented over 77 per cent of the series. The site of implantation was the left tube in 56 per cent, and the ampulla was involved in 67 per cent of the cases. In a majority of the women an inflammatory process was determined, and the cause of the second ectopic pregnancy was the same as in the first.

Recommendations for management are conservative, surgery being restricted to the cases presenting an involved tube, unless specific findings indicate bilateral resection. The ovaries and uterus are preserved when possible, for maintenance of the endocrine balance.

EDITH B. FARNWORTH, M.D.

Chesterman J.: On the Treatment of Placenta Previa. *Med. J. Australia*, 947-949.

An analysis of the treatment of 115 patients with placenta previa who were admitted to the Women's Hospital Crown Street Sydney forms the basis of this article.

The more babies one saves in cases of placenta previa, the greater is the maternal mortality. The converse is also true—that by concentrating on the welfare of the mothers an undue number of the babies are lost.

TABLE I.—PLACENTA PREVIA SOME COMPARATIVE STATISTICS

Source	No. of cases	Maternal deaths		Fetal deaths	
		No.	Per cent	No.	Per cent
Eleven teaching hospitals in Great Britain (F. J. Brown)	1,793	123	5.9	1,650	54
Women's Hospital, Melbourne (1934 to 1944)	156	10	6.4	30	19
Royal Hospital for Women, Sydney (1913 to 1946)	130	1	0.8	29	22
Women's Hospital, Crown Street, Sydney (1935 to 1946)	111	9	8.1	23	21
C. H. Macfarlane (Belfast) (1917 to 1941)	181	—	2.2	43	24
Leonard Phillips (Queen Charlotte's Hospital) (1933 to 1946)	143	—	—	54	38
Josephine Barnes (University College Hospital) (1917 to 1941)	40	—	0	12	30

Placenta previa was classified as lateral if the placenta occupied in part the lower uterine segment marginal if it came to the edge of the internal os, and central if it completely covered the internal os at the onset of labor.

METHODS OF TREATMENT

Watchful expectancy. If active treatment to empty the uterus is started at the first hemorrhage, many premature or nonviable infants will be delivered with little chance of survival. To follow a method of watchful expectancy, it is absolutely essential for the patient to be in a well equipped hospital where active treatment can be given at a moment's notice. No vaginal examination should be made until a more serious hemorrhage or repeated hemorrhages make it imperative. In those cases in which the fetus is reasonably mature, either dead or alive, there is no need for this delay.

Hemorrhage from a laterally situated placenta previa is often controlled by the onset of labor and no further treatment is necessary.

Active methods of treatment

- Artificial rupture of the membranes
- The application of Willett's scalp traction for cephs, to which a weight is attached
- The use of a vaginal pack (alone, or followed by another procedure when the os is sufficiently dilated)
- Compression of the placenta by the half breech
- The introduction of a hydrostatic bag
- Cesarean section

The fetal mortality rate among those capable of surviving is 42 per cent. The best results were obtained when lateral placenta previa was present (38% of fetal deaths), and the next best when the placenta was centrally placed (57%) because of the higher incidence of treatment by cesarean section. The highest mortality rate occurred when the marginal variety of placenta was present.

ANALYSIS OF TREATMENT

In 56 cases of central placenta previa, 88 cases of marginal placenta previa, and 8 cases of lateral placenta previa, the hydrostatic bag was not used at all.

No special treatment was employed in 49 cases, with fetal death in 22.

If the patient is in labor hemorrhage is still occurring, and the placenta is not lying centrally artificial rupture of the membranes is often all that is necessary. This was employed in 19 cases with 9 fetal deaths.

Willett's forceps were applied to the scalp in 33 cases with 21 fetal deaths (65%).

Summing up these three relatively simple methods of treatment, we find that they were employed in 100 cases with the same fetal mortality rate as the average for the whole series. They were used in 4 cases

of central placenta previa with no live babies. The high fetal death rate in the 47 cases of marginal placenta previa (about 70%) suggests that in some of them at least other methods of treatment might have given better fetal results without increasing the maternal risk too much.

The group of patients (47) treated by plugging with the half breech included all those in whom a fetal leg was pulled down to control hemorrhage. The fetal mortality rate was extremely high (91%).

The author believes that some of these patients might have been treated better by cesarean section. The author gives the best result for the baby and in this series it was safe for the mother. To reach the consensus of opinion has been swinging steadily in favor of cesarean section.

The large majority of these patients are multiparas, and consequently a scar in the uterus is of less importance than it would be in a primigravida. In such cases, with free use of blood transfusion and chemotherapy, the risk of cesarean section to the mother may be less than the risk of vaginal section. The shock, blood loss, and risk of infection are unavoidable in penetrating the placenta to pull down a leg can be great. The operation was performed in 70 cases with 18 fetal deaths. The classical operation was used in practically every case. The author prefers a combination of local anesthetic infiltration of the abdominal wall down to and including the incision of the peritoneum and pentothal sodium.

DANIEL G. MORROW, M.D.

Henderson D. N. The Obstetric Management of Pregnancy Complicated by Heart Disease. *Am J Obst* 1947 53 494.

The author reviews 200 cases of pregnancy complicated by heart disease: 100 by rheumatic heart disease, 7 by congenital heart disease, and 3 by degenerative heart disease.

Some of the cases were under a special management plan and these were divided into three groups according to the severity of the disease. The patients reported for examination every 3 weeks, and were seen by the cardiologist every 4 weeks. All patients were advised to rest a minimum of 12 hours daily and this was increased as the pregnancy progressed or the exercise tolerance diminished. If adequate rest could not be obtained at home, the patient was sent to the hospital. Most patients in Group II, with moderate to severe impairment of exercise tolerance, were advised to come into the hospital for confinement. Patients were warned of the seriousness of upper respiratory infection and advised to take more than usual care if such infection occurred. When possible, the normal weight gain was limited by suitable diet to 15 pounds. If the patient was obese, an effort was made to prevent any gain in weight. The development of signs of the late toxemias of pregnancy was considered serious, and immediate admission to the hospital was recommended for even mild degrees of albuminuria and hypertension.

Thirty patients had their pregnancies terminated because of heart disease, and 170 reached the period of viability. In 40 of these the onset of labor was premature, and this resulted in a fetal mortality of 17 per cent. The maternal mortality rate for the whole group was 4 per cent and for the patients under control of the management plan 2 per cent. The average age at death in the whole series was 38.8 years, 1 year less than the average age at death of 56 consecutive female patients proved at autopsy to have died from rheumatic heart disease not associated with pregnancy.

During recent years heart disease has not been considered an indication for cesarean section. One hundred and twenty-eight consecutive women with heart disease have been delivered vaginally. Cesarean section has been necessary on only 3 occasions and was performed only for obstetric indications.

JOHN R. WOLFF, M.D.

De Giorgi L.: Cancer of the Lung in Pregnancy. (*Il cancro del polmone in gravidanza*) *Arch ital gin* 1946, 51 330.

A 45 year old woman in the initial period of her eighth pregnancy suffered a sudden hemoptysis, emaciation. Pleuritic attacks a year previously had led to a diagnosis of pulmonary tuberculosis. The roentgenologic examination disclosed extensive cavitation of the left lung and evidence of nodule formation in the right lung. Pneumothorax on the left led to partial collapse of the left upper lobe. The lower lobe remaining densely shadowed and immobile. Premature labor at the seventh month of the pregnancy resulted in the birth of an immature child which died 3 hours after birth. Following the labor the general condition of the already precariously ill patient became worse, there was rapid accentuation of the respiratory difficulty and death 2 weeks later.

Autopsy uncovered an extensively adherent infiltrated and cavitated left lung and similar condition on the right side. The infiltration proved to be of a carcinomatous character involving the bronchi, blood vessels and lymph glands diffusely. Similar histologic characteristics were noted in a nodule in the left breast, the thyroid, left suprarenal gland, hypophysis, and right ovary. The extensive nature of the pulmonary lesion and the polymorphous character of the invading cancer cells—so characteristic of bronchial carcinoma—and the history of pleuritic manifestations suggested primary pulmonary carcinoma with secondary metastasis to the other organs.

The two remarkable and instructive facts with reference to the effects of pregnancy on the growth and metastases in this case were the apparent accelerative effect of the pregnant state on the growth of the tumor and the apparently elective character of the metastases. The author does not try to decide if the dissemination of these metastatic processes can be explained on the basis of the increased blood supply to the endocrine organs during preg-

nancy or whether a peculiar predisposition of the cellular substrate of the involved organs is involved. In any event, the author thinks that his case strikingly illustrates the difference between the theory of clinicians, who are rather unanimous in asserting that pregnancy has a deleterious influence on the growth and metastases of neoplasms, and that of experimental researchers, who tend to show that the hormones predominant in the process of pregnancy (prolan) have an inhibitory effect on certain types of new growths.

JOHN W. BREKIDAN, M.D.

Falconer, B.: A Study of the Pathology of Habitual Abortion. *Acta obst. gynaec. scand.* 94b, 26 496.

The present report concerns 33 cases classified as habitual abortion. In each case an attempt was made (on the basis of history, physical findings, semen examination, and endometrial biopsy) to establish the etiology. Four of the cases were discarded because each patient had had normal deliveries between several abortions.

Of the remaining 29 cases, the author concludes that in 4 patients the etiology of the miscarriages was on the basis of previous pelvic surgery or infection. In 3 there were physical abnormalities of the pelvic organs. In 3 patients abnormal semen was responsible and 4 patients were found to have an abnormal endometrium.

In the last of the groups there were cystic glandular hyperplasia in 1 case, tuberculosis in 1 case, and dilated cystic glands in 3 cases indicating ovarian deficiency.

J. ROBERT WILLSON, M.D.

LABOR AND ITS COMPLICATIONS

Rohlee, M. A.: Morbidity Associated with the Induction of Labor. *Am. J. Obst.*, 947 53 38.

Does the induction of labor increase maternal morbidity? Five hundred cases in which labor was induced by medical and mechanical means are reviewed and it was found that a marked increase in morbidity may result from such methods.

This increase in morbidity is caused by forcing labor before the cervix, lower uterine segment and uterus have been prepared for labor. The author believes that induction of labor after spontaneous rupture of the membranes may be a dangerous procedure. For the management of contracted pelvis, pelvic disproportion, and postmaturity induction has little or no usage.

Elective induction of labor which would have occurred in from 24 to 48 hours later gives little or no morbidity. Such elective induction is of little or no obstetric advantage but rather has convenience and order as its justification. The morbidity incurred by induction of labor must be evaluated against any questionable advantages of such management. This means that induction of labor merits obstetric usage mainly in the management of the toxemic patient, including the diabetic. The character and results of induced labor approach those of natural spontaneous labor only when the induced labor precedes by 48 hours, or less, the time when spontaneous labor would have occurred anyway.

JOHN R. WOURT, M.D.

Odeh, L. D., Randall, J. H., and Scott, G. W.: Prolonged Labor. *J. Am. M. Ass.*, 947 33 735.

In a series of 25,824 deliveries the authors found prolonged labor in 3.7 per cent. 66.9 per cent of the patients were primigravidae, 29.3 per cent had operative delivery, and 25.5 per cent had a febrile postpartum course. The maternal mortality rate was 0.7 per cent and the infant mortality rate was 10.4 per cent (largely due to intracranial hemorrhage). The maternal deaths were all attributed to puerperal infection.

The majority of these patients had uterine inertia rather than pelvic disproportion or abnormal presentation. Whereas no conclusions are derived in relation to the etiology of inertia, it is suggested that an abnormality of innervation or failure of the proper muscular response is the underlying mechanism. Furthermore, certain emotional disturbances may well play a role in this disturbance.

The authors believe that two separate courses are responsible for the control of blood loss following the separation and delivery of the placenta. The first is retraction, which occurs in the innermost muscular layers just beneath the decidua. The second is contraction of the remaining uterine muscle, which causes intermittent ischemia and thus stimulates thrombosis. The most interesting observation was that in this group postpartum hemorrhage occurred in 7.6 per cent as against 4.3 per cent in the so-called normal labors. Further it was found that in the patients who had had operative delivery the incidence rose to 10.5 per cent but fell to 6.4 per cent in the spontaneous deliveries. Therefore a conservative attitude in the management of prolonged labor with a particularly careful conduct of the third stage of labor is recommended.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Mathé, G. P.: Unilateral Renal Tuberculosis. *J Urol* Balt., 1947 57 451

The author describes the management of the nephrectomized patient

The author reviews 98 cases of renal tuberculosis to emphasize the importance of periodic postoperative cystoscopic examinations with the view of reducing the mortality and increasing the number of permanent cures. He suggests that the type of nephrectomy depends on the extent of the pathological process. If the ureter is involved a nephroureterectomy is done either primarily or the ureter is removed later if it is uninvolved simple nephrectomy is done. In critically ill patients complicated by perinephric abscess incision and drainage of the abscesses may be followed in 2 weeks by nephrectomy. The author lavages his wound with saline solution and then introduces from 2 to 4 gm. of sulfa drugs and 100,000 units of penicillin in 100 c.c. of saline solution which he believes is definitely helpful in preventing break down of wounds.

Following nephrectomy there is often persistence of tuberculous cystitis which necessitates long term cystoscopic treatment of ulcers and stricture of the intramural segment of the ureter. In this series stricture of the opposite ureter was found in 28 patients it was treated by dilatation. Intractable cystitis is characterized by sclerowing cystitis and ulcer formation. This condition was so intolerable in 4 instances that diversion of the urinary stream was necessary.

Analysis of the 98 cases reviewed revealed the following:

1. Tuberculosis of the kidney occurs less frequently in the western part of the United States than elsewhere.

2. Stone occurred in 7 cases with renal tuberculosis, in 3 with cancer and in 3 with renal hypertension.

3. The mortality rate in 81 cases following nephrectomy for unilateral tuberculosis was 1.2 per cent.

4. Twenty-eight of the 81 patients operated upon had ureteral stricture which emphasizes the importance of postoperative observation and treatment.

ROBERT O. BEADLER, M.D.

Bondy P. K., and Barnwell C. H. Chronic Typhoid Pyonephrosis. *J Urol* Balt., 1947 57 742.

The problem of the management of the chronic urinary typhoid carrier seldom confronts American physicians today. This is partly because of the recent great reduction in the incidence of typhoid fever in the United States and partly because the renal carrier state occurs only rarely after acute typhoid

fever. If surgical treatment can eliminate the source of the organisms in such a case without harm to the patient the major objective of the control of typhoid carriers will be achieved.

The authors present a case of chronic typhoid pyonephrosis of long standing in which the urinary carrier state was cured by surgical extirpation of the involved kidney. The patient, a 32 year old soldier had had typhoid fever at the age of 12 years. He had had no urinary symptoms until 4 years before admission when nocturia became noticeable. Urinalysis revealed innumerable white blood cells and a slight trace of albumin and a culture yielded the *Eberthella typhosa*. Urologic study revealed the disease to be confined to the right kidney which presented the picture of pyonephrosis with a stone impacted in the ureteropelvic junction. A right nephrectomy was done and the convalescence was uneventful. Repeated urine cultures were negative.

Pyonephrosis as a complication of typhoid fever is not a common occurrence. The reported cases can conveniently be divided into 3 groups: those occurring during the acute, initial attack of typhoid fever; those occurring as a result of superimposed typhoid infection upon a previously occurring renal disease; and those which because of their chronic character their lack of symptoms and their persistent bacilluria, constitute the silent carrier group. In the series which the authors collected from the literature 7 of 12 in the first two groups died. However all those in the asymptomatic carrier group recovered after nephrectomy.

Although the authors' patient had been a carrier for 20 years, not a single secondary case had been produced, either within his family or among his close associates.

JOSEPH E. MAURER, M.D.

Harvey N. A.: Renal Tumors. *J Urol* Balt., 1947 57 669

In the opinion of the author the theory of Grawitz is untenable as an explanation of the histogenesis of renal cortical malignancies. The early literature is reviewed, and the author presents clinical and pathological data on 50 renal tumors and 8 incidental "hypernephroid" tumors found in the course of 4,520 autopsies and 39,857 surgical operations at the Rhode Island Hospital, Providence from 1929 through 1944. Thirty nine of the tumors were surgical specimens while the remaining 19 were removed at autopsy. It is pointed out that renal tumors constitute about 2 per cent of all tumors in adults and about 20 per cent of those in children. In this series there was a 66 per cent incidence of cortical adenocarcinoma, a 26 per cent incidence of carcinoma of the pelvis (including 1 case of epidermoid carcinoma) and a 6 per cent incidence of Wilms tumor, 2 per cent of the cases eluded classification. Seventy per cent of the cases were in males.

nancy or whether a peculiar predisposition of the cellular substrate of the involved organs is involved. In any event, the author thinks that his case strikingly illustrates the difference between the theory of clinicians, who are rather unanimous in asserting that pregnancy has a deleterious influence on the growth and metastases of neoplasms and that of experimental researchers, who tend to show that the hormones predominant in the process of pregnancy (prolan) have an inhibitory effect on certain types of new growths.

JOHN W. BENDIXEN, M.D.

Falconer, B.: A Study of the Pathology of Habitual Abortion. *Acta Obst. Gyn. Scand.* 946, 26 496

The present report concerns 33 cases classified as habitual abortion. In each case an attempt was made (on the basis of history, physical findings, semen examination and endometrial biopsy) to establish the etiology. Four of the cases were discarded because each patient had had normal deliveries between several abortions.

Of the remaining 29 cases, the author concludes that in 4 patients the etiology of the miscarriages was on the basis of previous pelvic surgery or infection. In 3 there were physical abnormalities of the pelvic organs. In 3 patients abnormal semen was responsible, and 4 patients were found to have an abnormal endometrium.

In the last of the groups there were cystic glandular hyperplasia in 1 case, tuberculosis in 1 case, and dilated cystic glands in 2 cases indicating ovarian deficiency.

JOSEPH E. MARSH, M.D.

Harvey, N. A.: Renal Tumors. *J Urol* Balt., 1947 57 669.

In the opinion of the author the theory of Grawitz is untenable as an explanation of the histogenesis of renal cortical malignancies. The early literature is reviewed, and the author presents clinical and pathological data on 50 renal tumors and 8 incidental "hypernephroid" tumors found in the course of 4,549 autopsies and 39,857 surgical operations at the Rhode Island Hospital, Providence from 1929 through 1944. Thirty nine of the tumors were surgical specimens while the remaining 10 were removed at autopsy. It is pointed out that renal tumors constitute about 2 per cent of all tumors in adults and about 20 per cent of those in children. In this series there was a 66 per cent incidence of cortical adenocarcinoma, a 26 per cent incidence of carcinoma of the pelvis (including 1 case of epidermoid carcinoma) and a 6 per cent incidence of Wilms tumor; 2 per cent of the cases eluded classification. Seventy per cent of the cases were in males.

The "classic" triad of hematuria, pain, and a mass was found in 17 per cent of the cases. Microscopic urine studies in 44 cases revealed red cells in 7 per cent whereas the incidence of gross hematuria in the whole series was 59 per cent. Proteinuria was the most frequent urinary finding and occurred in 93 per cent of the cases. Hematuria was the most common initial or early symptom in the operable cases while metastatic symptoms were the most frequent early features of the inoperable series. Pain was classified as primary when limited to the back or flank, and as secondary when it was due to metastases. The presence of a mass is usually a late symptom. Typically the mass is located in the flank, it is firm, smooth, rounded, moves freely with respiration, and is not particularly tender.

Urinary symptoms were present in 40 per cent of the operative cases and consisted of dysuria followed by frequency, urgency, pain, and burning, in that order.

The value of intravenous pyelography as a means of diagnosis is stressed.

Metastatic lesions appeared in the following order of frequency in the lungs, bones, liver, lymph nodes, renal veins, suprarenals, opposite kidney, pleura, central nervous system, and pancreas. More than 50 per cent of the metastatic lesions occurred in the lungs. Tumor embolism is believed to be the most common mechanism of spread and is substantiated by the high incidence of pulmonary lesions.

Immediate surgery without irradiation is considered the therapeutic procedure of choice, and mention is made of the fact that the surgical mortality in fixed tumors is sufficiently high to warrant discontinuance of the operative procedure in cases in which the situation is fixed. In such cases irradiation may afford a prolongation of life, as relief in pain. It is pointed out that immediate postoperative irradiation deserves serious consideration, since in terms of five-year survival, the percentage was 42 per cent as compared to 31 per cent in cases in which irradiation preceded surgery.

lively the third child died from pertussis complicated by pneumonia, and the fourth died from uremia one year following the operation. The last child had lost a solitary kidney.

The author describes the preoperative and post-operative routines in detail and briefly discusses his operative method, which is a modification of the Coffey I technique.

It is suggested that the operation be performed during the first year of life rather than later since infants stand the operation infinitely better and there is less renal damage present at that time. The technical difficulty associated with the presence of smaller structures is not considered a contraindication. The ectrophic bladder is removed at this time while plastic procedures on the penis are delayed until the child is 5 or 6 years of age.

This article clearly presents a sound logical reasoning to support the author's conclusions and the material is presented in a concise, factual manner.

ROBERT LACH, JR., M.D.

BLADDER, URETHRA, AND PENIS

Moskale, U.: Telangiectatic Granulations of the Urinary Bladder following Radiotherapy for Cancer of the Uterus (Les granulations télangiectatiques capillaires de la vessie à la suite de la radiothérapie pour cancer de l'utérus). *J. seral. med.*, Paris, 1946, p. 33-3.

Early and late lesions can occur in the urinary bladder following radium therapy and roentgen therapy for cancer of the uterus, especially if there have been errors in technique or if the dosage has been very high.

The early reactions appear during treatment and are represented by the common but harmless catarrhal cystitis which rapidly disappears and seldom leaves radionecrotic ulcers. One can also notice extravasations of blood and a hyperemia of the trigone 2 or 3 weeks after completion of radiotherapy. These were classified by Korchow as erythema of radiation.

The late reactions are less common, usually occur from 2 to 4 years after radiotherapy, and are classified as reversible and irreversible.

The irreversible lesions, thoroughly characterized by atrophy of the bladder and by extensive alterations of the veins and arteries, are permanent.

The reversible lesions caused by hypotrophic technique are the radionecrotic ulcers, which erode the bladder wall to such a degree that severe hemorrhages or fistulas may develop.

In addition, radionecrotic ulcers, tiny but numerous, have been observed on the mucosa. These were called "humbeartige Tubercles" by Schneider and "humbeartige Tubercles" by Veil.

The author has had the opportunity of examining 10 patients with lesions called telangiectatic lesions because of their gross appearance and their shape structure. They became the subject of his study.

The 10 women observed were referred to the author by the Radium Institute of Bologna where they had been treated for cancer of the uterus. The passage of a few drops of blood at the end of micturition associated with some urinary disturbance made the referring radiotherapist believe that either the cancer had directly invaded the bladder or metastases had occurred. Following discovery of the lesions each patient was closely observed and repeated cystoscopic examinations with biopsy were performed until the lesions disappeared.

The oldest patient was 70 years old and the youngest was 36 years old. The average age of the patients was about 60 years. Of these patients 9 presented an epithelioma of the cervix and 1 an epithelioma of the fundus. Nine patients were treated with radium and roentgen rays. In 1 case direct x ray therapy by intracavitary contact was substituted for radium. For routine treatment radium was applied into the vaginal cul de sac by means of 2 tubes of 10 mgm each, a filter of 2 mm. of platinum was used. In the uterine cavity tubes of 10 mgm. of radium single or also used at times. In the last type of treatment the filtration was 1 mm. of platinum or half that used in the vaginal cul de sac.

Early reactions occurred in 3 of the 10 patients and were represented by rectal tenesmus and cutaneous epitheliolysis. Only 1 patient developed cystitis while under treatment. The time of appearance of the granulations was between 17 and 44 months after completion of the treatment. The symptoms responsible for bladder investigation were pain usually at the end of micturition and hematuria which always was terminal.

In 6 cases the urinalysis was negative while in 4 cases microscopic hematuria and pyuria of no significance were recorded. Cystoscopy revealed a diffuse cystitis in 3 cases and typical radionecrotic ulcers in the other cases. The bladder capacity was within normal limits except in the 3 cases of cystitis. Subsequent cystoscopies as well as clinical follow ups of the patients have shown that the urinary symptoms and most of the granulations disappear within 3 months. The radionecrotic ulcers healed in approximately the same period of time. Following disappearance of the lesions the mucosa of the bladder appeared pale and atrophic and was often the seat of venous ectasias.

The author then described the pathology of the lesions. Grossly the granulations were prominent, rounded granular hnds sometimes composed of very other. Their bright red color contrasted with the pale and atrophic mucosa. They were comparable in size to a pinhead or flax seed but, as a rule they were of uniform size and very often occurred in groups sometimes quite numerous. They did not fade in the distended bladder but as seen in 7 cases a hematic subepithelial suffusion took place.

The granulations were usually found in the floor of the bladder beyond the interureteral ligament. They

were never observed to occur in the apex nor in the lateral walls of the bladder. Redness and edema of the diffuse cystitis type were sometimes associated with these lesions. In 3 patients the granulations surrounded the typical radionecrotic ulcers.

Microscopically these granulations were covered by an almost normal vesical epithelium which had the tendency to undergo metaplasia and so form the oecia of Limbeck and other arrangement of cells having somewhat the appearance of tubular glands.

These formations were described by Limbeck in 1887 and successively by von Brunn, Lendorf and others. They were thought to consist of epithelial nodules detached from the submucosa of the kidney pelvis the ureters and the bladder. Markwald Badke Barbacci Simelew thought them to be congenital. Today it is the opinion of Aschoff, Del Busco, Dionisi Pepere and Businco that they are due to a chronic inflammatory process or a chronic irritation of the mucosa. Following such irritation the epithelial bands and isolates them, and thus the nodules of Limbeck are formed. These were never observed in young patients.

If the stimulation continues and if the conditions of nutrition remain favorable the nodules of Limbeck may progress further. The central cells degenerate and the cells forming the wall of the cavity become transformed into a secretory epithelium forming cysts. Such would be the origin of the cystic cystitis. Furthermore according to Businco the formation of glands (glandular cystitis) and even of adenomas and adenocarcinoma of the urinary tract may follow by successive steps.

The loose connective tissue of the submucosa in which can be seen a more or less distinct infiltration of round cells discloses the presence of numerous tortuous and extremely dilated capillaries which give the tissue an angiomatous appearance. A few of these vessels extend to the basal membrane of the epithelium, which explains the bright color of the granulations. Sometimes a hematic suffusion is surrounded by a few of these vessels. The endothelium of the capillaries has normal characteristics. In 1 instance the author observed the presence of thrombi in the lumens. Numerous leucocytes were also seen in the capillaries because of stagnation of the circulation in such distended vessels.

At this point it was noted that the dilatation of the capillaries really exceeded the degree of vasodilation observed in pure inflammation and actually reached the stage of telangiectasias. The small thrombi in the ectatic capillaries may indicate a transitional stage toward the disappearance of these formations.

When the findings are such as described there is no difficulty in making the diagnosis. These formations have a great similarity to the ruby spots of the skin. As a rule the inexperienced endoscopist, confronted with such a picture suspects a neoplastic invasion or metastasis. Such suspicion first suggested by the history of a cancerous lesion is further substantiated

when the histologic examination reveals the nodules of Lillbeck which may simulate neoplastic buds. However, the picture of the neoplastic infiltration of the bladder is well defined. In most cases one can observe a solid salient mass surrounded by a bullous edema and very often characterized by the presence of ulcerations varying in depth, with irregular bases and with a definite tendency to bleed. In contrast to these are the radionecrotic ulcers which occur in an almost normal mucosa. They are characterized by regular edges and a clean base, and they very seldom bleed. They are not surrounded by the bullous edema but by telangiectatic granulations. These lesions must be differentiated from purpura of the bladder, hemorrhagic cystitis, and submucosal suffusions of blood produced by intravesical maneuvers.

Purpura of the bladder varies from the telangiectatic granulations because its spots are of various sizes and are flat and red or dark blue. The presence of a cutaneous purpura confirms the diagnosis.

Submucosal suffusions of blood due to endoscopic maneuvers appear as flat spots with irregular outlines which change during observation.

Therapy is exclusively symptomatic and consists of preventing and treating the cystitis. After the diagnosis of telangiectatic granulations has been established, urinary antiseptics should be prescribed. Depending upon the presence or absence of dysuria, morphine is indicated. One must avoid excessive distention of the bladder in order to prevent rupture of the capillaries with ensuing hemorrhage. Should hemorrhage occur, electric coagulation of the bleeding points should be contemplated.

The etiology of these granulations is problematic. Are they the result of a common inflammatory process or do they represent a reaction of the bladder to radiotherapy? Several factors confirm the latter theory. First such granulations have been observed in some women who have been treated with radium therapy for cancer of the uterus and have developed radionecrotic ulcers associated with these granulations in the expected period of time. Second, such formations have appeared exclusively in patients subjected to heavy dosage of therapy however with out over-treatment. Finally the capillary granulations occur only in that area of the bladder mostly exposed to the action of the rays. Furthermore, the histologic structure of the granulations forces one to associate these lesions with those produced by the action of radiotherapy on vessels.

On the basis of the infiltration of the round cells, can such a clinical picture be a chronic cystitis in which the capillaries dilate and proliferate? The macroscopic as well as the microscopic aspects of the lesions justify such therapy. The cystitis and the pyuria observed in 3 cases by the author must be considered as co-existent findings, the development of which is perhaps enhanced by these granulations. These lesions are then the result of the irritation produced by radiotherapy.

What rays, radium or roentgen, can be regarded as the responsible irritating agent? Several authors

(Schroeder von Ottow Neef) point out that the late lesions following roentgen therapy appear as a rule in the apex of the bladder while radium exerts its action on the floor of the bladder because the radium tubes deposited in the vaginal cul de sacs and the uterine cavity are closer to the floor than to the other area of the bladder. All the cases reported by the author were subjected to both types of therapy roentgen and radium.

It is not possible, then, to determine if these telangiectatic granulations can be attributed to the action either of radium therapy or roentgen therapy. Nevertheless, one must consider that several patients treated at the Bologna Institute of Radium with heavy doses of roentgen therapy have never developed, even years after the completion of the treatment, urinary symptoms or lesions of the bladder similar to the ones just reported by the author. It is more convincing to remember that these lesions are due to the combined action of both types of irradiation. The author concludes that these telangiectatic granulations do not justify any change in dosage of irradiation because the cure of the patient constitutes the principal goal of such therapy.

GERARD GARNOW, M.D.

Alvarez Zamora, R.: Sarcoma of the Bladder (Sarcoma de vejiga). *Arch. esp. urol.*, 947 3 7

Alvarez Zamora reports 4 cases of sarcoma of the bladder. The first occurred in a 72 year old male who had frequent hematuria and signs of urinary retention for 3 weeks before admission. On rectal palpation an irregular hard mass could be felt above the prostate. Infiltrating the right posterior wall of the bladder which by cystoscopy appeared to be a submucous tumor with almost complete integrity of the mucosa. A biopsy of the tumor revealed this to be a fibromyxosarcoma.

The second case, that of a 56 year old man with hematuria for 15 years which was previously diagnosed as a vesical polyp was treated by 5 consecutive electrocoagulations without any improvement. Cystoscopy disclosed a tumor of the bladder which histologically appeared to be a sarcoma of polymorphic cells combined with an epithelioma and a papilloma.

The third case that of a 56 year old man, presented polycythemia as the main symptom. At cystoscopy the condition appeared to be a submucous tumor. A subtotal cystectomy with bilateral iliac ureterostomy was performed. Histologically the tumor proved to be a fibrosarcoma.

The fourth case, that of a 32 year old man, presented a history of hematuria and polycythemia for 3 weeks. At cystoscopy a smooth, red, pediculated tumor about the size of a nut was found at the trigonum. This was resected with the electrocautery through an abdominal operation. Radium needles were placed *in situ* for 10 days. Histopathologically it proved to be a lymphocytoblastoma. The patient has been seen without recurrence after 2 years.

WILLIAM E. ROBERTS, M.D.

Kirz, E.: Ostitis Pubis after Suprapubic Operations on the Bladder *Brit J Surg.*, 1947 34 272

Ostitis pubis after suprapubic operations on the bladder appears to be a clinical entity. In a series of 174 patients the incidence of ostitis pubis was 3 per cent.

Three to 6 weeks after operation the patient complains of pain in the region of the symphysis pubis. This pain may extend toward the perineum and radiate down the inner side of one or both thighs. If the man is still in bed the slightest movement of the thighs or attempts to turn over or to sit up will cause pain. If he is up walking is difficult or impossible. In other cases standing may be easier than sitting the latter causing unbearable pain over the tubera ischii. Urinary symptoms are rare, but terminal dysuria occurs in cases in which the origin of the perineal muscles is involved similarly there may be pain on defecation. These symptoms may actually cause the patient to take to his bed again because only full rest will relieve them.

On examination the areas mentioned are extremely tender to touch. All active and passive movements of muscles originating from that part of the pelvis which is involved by the ostitis are limited and very painful. These muscles are at first spastic later in severe cases they may show great wasting. At times there may be some discharge of urine or pus from the lower part of the operation scar but no pathogenic organisms are obtained in culture. This discharge moreover does not seem an essential part of the trouble as it often occurs in cases showing no signs of ostitis pubis. Slight fever at the onset of symptoms is, however a characteristic feature. After major operations this area is usually the medial portion of the lower third of one or both corpora pubis. After minor operations fraying appears first at the upper corners of the pubic bone and in mild cases, the condition may be arrested at this stage. Most of the established cases, however later on show a definite spread involving variable amounts of pubic bone and ischium. The symphyseal cartilage may be absorbed giving the appearance of separation of the symphysis, and finally bony ankylosis may result. The formation of a sequestrum is the exception rather than the rule but areas of osteoporosis and osteosclerosis are seen later. Various explanations have been offered as to the pathogenesis. Two main factors appear to be essential in the production of the infection (1) leakage of infected urine into the retropublic space and (2) trauma both during and after operation.

The author advocates a method of operation to minimize this complication. The separation of the recti and pyramidalis muscles is carried out in the usual manner. Then about 3 cm. above the level of the symphysis a transverse incision 2 inches long is made through the anterior and posterior layer of the (continuation of the) transversalis fascia, prevesical fat, and vesical layer of the pelvic fascia. The lower flap is then dissected downwards off the anterior bladder wall for about 4 cm. and approximated with

two or three interrupted sutures to muscle at the lower angle of the wound. The two spaces are thereby securely shut off.

C. FRED GORMAN, M.D.

Marshall V. F. and Schnitman M.: Vaginal Cystectomy *J Urol* Balt., 1947 57 848

Vaginal cystectomy is done with the patient in a moderately exaggerated lithotomy position and the cervix is pulled down with a tenaculum to expose the anterior vaginal wall. A transverse incision is made completely through the vaginal wall approximately 2 cm. anterior to the cervix and 4 or 5 cm. in length. The cervix is separated from the bladder by inserting a finger into the loose tissues thus exposed between these 2 organs a common step in gynecological operations. From either end of this transverse incision parallel extensions are carried laterally and outward to the external sides of the labia minora. There is then a rectangular area of the anterior vagina which is outlined by the transverse incision anterior to the cervix the parallel lateral incisions and the vestibule. Gauze packing is placed in the vagina to control the moderate oozing after ligation of any actively bleeding vessels.

According to the extent of the lesion, the clitoris is not included in the next incision which encircles the urethral meatus at a radius of at least 3 cm. and includes at least the upper half of each labium minus as well as some of the labia majora. The removal of considerable labium majus not only provides a wider margin for tumor removal but greatly aids the exposure for future steps. This was carried down to the peritoneum of the pubis and the ends of this somewhat circular cut were joined to the ends of the lateral vaginal incisions. Numerous vessels usually required ligation at this stage but they are easily located.

The upper portion of the mass to be removed was separated from the peritoneum until the pubic arch was visualized. An incision was then made immediately adjacent to and parallel with the bony arch through the triangular ligament. The fingers could now be inserted easily into the loose tissues of the space of Retzius which was opened widely and bluntly. If the fingers are kept close to the peritoneum the venous plexus between the urethra and bladder neck and the symphysis are largely avoided and removed as part of the specimen. Clamps are applied to the urethra or bladder neck for traction. A straight prostatic tractor through the urethra may be used, but in some cases it may traumatize the neoplasm excessively. The lateral supports of the bladder are now on tension and are clamped and transfixed on either side until the ureters are cut across. Up to this point vision is excellent and the danger of injuring important structures seems almost nil, since urinary diversion is obviously prerequisite to cystectomy. In order to prevent possible clamping of the bowel in the cul-de-sac, or clamping the uterine arteries, and to avoid unnecessary lateral dissection the peritoneum is now identified and

opened. This is usually most easily accomplished by pulling down on the dome and dissecting slightly to one side of the midline to avoid the possibly adherent area of the urachus. The peritoneum is peeled off the posterior bladder wall as far as it will easily go in order to cut under vision the urachal remnants when this is necessary.

In some instances this blunt dissection is so easy that the previous ligations are met without further need of clamping in which case it is not necessary to open the peritoneum. The separation of the highest portions of the bladder from the peritoneum is, thus, far the only difficult step, since it is the most remote dissection and in an area with few definite landmarks. However if the slightest difficulty is encountered, a well exposed area of peritoneum is carefully oriented. Then with a finger inside of the peritoneum the remaining tissue to be clamped and ligated are at once evident, which prevents unnecessary lateral dissection and provides excellent orientation. Also the possibility of including bowel in a clamp is easily avoided by this maneuver. A patch of peritoneum on the posterior bladder wall is frequently removed with the specimen. The peritoneum is closed with a continuous suture.

Chronic catgut sutures are placed in the neck of the cervix and into the peritoneum and ligaments of the pubic arch. This moves the uterus and cervix down to plug the space previously occupied by the bladder. One rubber drain is placed on either side of the cervix and into the retroperitoneal space and the external ends are sutured to the vulva. The vaginal wall incisions are now approximated with interrupted single catgut sutures and the skin is placed for from 5 to 7 days. Penneal flushes are given daily but no douches, as the latter might force material into the operative space.

JOHN A. LOSE, M.D.

Minck, Bernard D.: and Zheutlin, Bertram: Penile Ulcer Caused by the *Micrococcus Tetragenus*. *Bull. Johns H. Hosp.* 947 80 98.

The *micrococcus tetragenus* is a gram-positive coccus frequently associated with the tubercle bacillus and the sputum, especially with the tubercle bacillus and with Pfeiffer's bacillus. The organism has distinct bacteriological characteristics. It is ordinarily not virulent and the infection follows a predisposing condition, usually an infectious disease, which reduces the resistance of the host.

The disease begins abruptly and the severity of its course is variable. There are chills, remittent fever, leukocytosis, and occasionally splenomegaly. The infection may become localized and cause pneumonia, arthritis, empyema, meningitis, and endocarditis. The occurrence of perinephric abscess and of pyosalpinx has been reported.

The authors report the first case of penile ulcer caused by the *Micrococcus tetragenus*. A 39-year-old white soldier suffered an injury to his penis by impact from a fall. He admitted having practiced fellatio

about 20 days before the injury. He presented swelling of the glans penis with an excoriated ulcer at the meatus, without induration or discharge. Laboratory studies were essentially negative, but anaerobic cultures produced a pure growth of organism identified as the *Micrococcus tetragenus*. The lesion improved after 4 weeks of treatment with zinc peroxide, azochloramide, penicillin and sulfonamide. Normal urinary and sexual functions were regained.

JOSEPH E. MAURER, M.D.

GENITAL ORGANS

MacDonald, B. A., and Powell, R. E.: Gelfoam in Prostatic Surgery. *J. Urol.*, Balt., 1947 57 81.

The authors used gelfoam as a hemostatic agent in 15 cases of suprapubic prostatectomy by the following method:

The gelfoam was prepared during the "setting-up" stage of the operation, soaked in a solution of thrombin in which it was kneaded to expel air from its numerous pores. Following removal of the gland, major arterial bleeding was controlled by ties, then the prostatic fossa was completely filled with gelfoam. Four or 5 pieces of the material are placed into the prostatic fossa and then suction is applied to draw the blood up into the interstices of the foam where a fibrin coagulum is formed. The cavity is filled as snugly and completely as possible with any amount of gelfoam necessary. The foam is pressed well under any encircling rim of the bladder mucosa which helps to retain the substance in place. A small straight sump tube is fastened high in the fundus of the bladder away from the prostatic cavity and simple bedside or suction drainage is employed.

In the authors' group of cases hemostasis was satisfactory in all save one case, in which there was probably arterial bleeding. There were no clots formed and the drainage was clear in from 48 to 72 hours. It is believed that with the use of gelfoam or similar substances, the mortality rate in prostatic surgery should be considerably reduced.

ROBERT O. BRANSON, M.D.

Mayor G.: Tuberculous Epitheliumitis and Its Surgical Treatment (Die Epitheliumitis tuberculosa und ihre chirurgische Behandlung). *Heft. chir. med.* 947 4 28.

In the Inselspital of Bern, Switzerland, 133 cases of tuberculous epitheliumitis were treated surgically in the urological department headed by Wildbolz. This number did not include the patients with the so-called nonspecific epitheliumitis that is, those with tuberculous disease elsewhere but no histologic findings of tuberculosis in the removed specimen. Excluded also from this number were those with primary local involvement of the testicle from primary local infection elsewhere. All but 26 of the 133 patients could be traced later. Of these 107 patients, 28 (26.1%) had previously been operated upon for renal tuberculosis, all of the latter are now well. Twenty six (24.7%) were operated upon later for

renal tuberculosis these also are all in good health. Two patients developed bone tuberculosis later and these are still under treatment. Four (3.6%) have died of generalized tuberculosis, and 6 (5.4%) of causes other than their tuberculous disease. The remaining 41 patients (38.4%) have remained well and have never shown any other evidence of the disease.

However these figures do not adequately portray the success attained in this material. In 73 of these patients the epididymitis represented the first evidence of the disease and in 32 of these (43%) tuberculous complications were found elsewhere later in 41 (57%) no tuberculous complications were ever found. Operation was instituted at once in all of these cases and in 60 per cent of them the single operation resulted in permanent cure of all the tuberculous manifestations. The author believes that this result was so dramatic that it pointed the way for a change in the method of treatment of tuberculous epididymitis.

The operation of choice has been epididymectomy or even epididymectomy with partial resection of the testicle because of the impact of unilateral orchectomy (castration) on the usually depressed psyche of these predominantly youthful individuals. There is, of course, also the possibility of bilateral involvement and the necessity of removal of the opposite testicle. As a rule the incision is placed rather high toward the base of the scrotum after preliminary ligation of the vas. The testicle is then pulled up into the wound and the epididymis is separated, care being taken to avoid injury to the testicle and the arteries supplying it. In the presence of scrotal fistula following the preliminary ligation of the vas the epididymis is removed en bloc with as much as necessary of the attached scrotal tissues to leave a clean wound. A scrotal drain may be left in place for a few days and the patient is ultimately discharged to a mountain resort for 1 or 2 months before being permitted to return to work. As a rule the postoperative course is symptomless. The patient's testicular foci (prostatitis seminal vesiculitis) begin at once to show that the condition is improving. In this material there have been no secondary operations on the prostate or vesicles. Preventive vasectomy was not done as the condition may become bilateral and then every effort must be directed to preserving the reproductive capacity of the young male patients. As a rule the surgical treatment preceded the instrumental examination of the urinary tract and no attempt at instrumentation was done until after healing of the secondary foci in the prostate and seminal vesicles occurred.

JOHN W. BRENNAN M.D.

Riba, L. W.: Operation for Varicocele. *J. Urol.* 1941, 104: 57-59.

Riba states that there are two anastomosing venous drainage systems. The deep system consists mainly of the internal spermatic vein, the ductus

deferens vein and the external spermatic vein. The superficial system consists of the superficial and inferior epigastric veins, the superficial internal circumflex veins, and the scrotal tributaries of the superficial and deep external and internal pudendal branches. These superficial veins communicate with each other and connect with the external spermatic vein of the deep system through the cremasteric branches at the external ring. On an anatomical basis excision of the internal spermatic vein without destruction of the anastomosing branches linking the deep and superficial systems would seem to be the operation of choice. The improved circulation should prevent further testicular atrophy.

Conventional varicoectomy frequently does not relieve the symptoms and at times the operation seems to aggravate symptoms. The author describes 23 cases in which excision of the internal spermatic vein was performed. Sixty five per cent of the patients were given sodium pentothal intravenously and spinal anesthesia. A 5 or 6 cm. incision was made over the left inguinal canal 1 cm. above the external inguinal ring (the latter should not be divided). Hemorrhage must be avoided. Eye surgery instruments are valuable. After exposure of the cord the inguinal portion of the vein is readily exposed by incision of the infundibuliform fascia immediately covering it. Without bleeding the vein in one or more trunks may be easily dissected away from the underlying spermatic artery. Three or more centimeters of the vein are resected. The cut ends are ligated with nonabsorbable sutures, and the fascia is closed transversely over them. A search is made for a hernial sac and, if present, a herniorrhaphy is performed. The fascia of the internal oblique muscle is sutured to the inguinal ligament (silk or cotton sutures are used for closure) and the scrotum is placed in a suspensory. The patient is kept in bed from 7 to 10 days. Scrotal amputations are unnecessary. Eighty symptoms and were satisfied. All of the varicoceles shrank after surgery. DAVID ROSENBLUM, M.D.

Engle, E. T.: The Testis Biopsy in Infertility. *J. Urol.* 1947, 57: 789.

Engle states that an understanding of the basic cause of azoospermia or oligospermia cannot be afforded by the sperm count alone. The testis biopsy affords important and frequently crucial information in these cases. The testis biopsy and semen analysis should be studied together. Each method is supplemental to the other.

In many cases of azoospermia there is a history of gonorrheal infection with bilateral epididymal occlusion. If the epididymis is found to be indurated on examination and there is a lesion in the lower portion of the duct of the azoospermia is known to be vasoeididymal anastomosis is desired. A testis biopsy is urgently indicated. The biopsy will indicate those cases in which the testes are actually producing spermatozoa and in which an attempted

TABLE I.—SEMEN ANALYSIS AND TESTIS BIOPSY

Semen analysis	Testis biopsy
Normal sample	
Azoospermia	With demonstrable occlusion Normal tubules Disturbed spermatogenesis b. Without demonstrable occlusion Normal tubules Progressive tubular fibrosis a. Germinal aplasia Spermatogenic arrest (no spermatocytes I)
1. Oligospermia	a. With high frequency of abnormal spermatozoa Incomplete maturation Progressive tubular fibrosis b. Inflammation and infection

anastomosis is justifiable and will eliminate those in which the testis itself is inadequate. A normal testis with adequate spermatogenesis may be revealed at biopsy even though there is bilateral occlusion.

The most frequent cause of azoospermia is mechanical blockage of the duct system of the testis. Primary atrophy associated with thickening and hyalinization of the wall of the seminiferous tubules is common even in young men. In old age testicular atrophy resulting from tubular fibrosis is common but this condition is not restricted to the older age groups alone. In the author's series of patients from 30 to 40 years of age, the lesion showed characteristic changes involving the tunica propria and the basement membrane of the tubule. The tunica propria showed an increased thickness due to lamination and hyalinization of the collagenous fibers. The basement membrane was demonstrably thickened, but to a lesser degree. The epithelium in various tubules showed several stages of atrophy and denudation. In tubules which were completely fibrosed no residual lumen and no epithelium were left. In the tubules with a lesser degree of atrophy all epithelium was lost at times except the Sertoli cells. Among the fibrosed tubules there were some with seminiferous epithelium containing several stages of spermatogenic cells. An occasional sperm head in the testis tubules was seen even in cases with no sperm in the semen specimens. No lesions were demonstrated in the arterial system of such testes. The interstitial cells were normal in number and secretory in appearance.

Because this is a lesion occurring in younger men, but found in increasing frequency in each successive decade, the author has called the condition progressive tubular fibrosis. There is no known cause for this type of fibrosis although it is presumably not of endocrine or nutritional origin. The process is apparently irreversible and there is no evidence that its course can be arrested. Fibrosis of the tubule in younger men implies no impairment of the androgenic function or hormone production.

Germinal aplasia is characterized by complete or almost complete absence of all cells of the germ cell

type, including the parent cells, the spermatogonia. The tunica propria is not thickened or hyalinized. The contour of the tubules is regular and they are not shrunken as in progressive tubular fibrosis. The only epithelial cell present within the tubules is the sustentacular cell of Sertoli. Because of the absence of cells of the germ cell type, this condition is called germinal aplasia. However, the term does not indicate whether this absence of germ cells is congenital or a result of later tissue injury.

The Sertoli cell of the testis tubule is recognized primarily by its nucleus. The nucleus is ovoid and has a brightly staining nucleolus. There is frequently a groove on the surface of the nucleus, which may give it the appearance of a grain of "puffed wheat." The cytoplasm of the Sertoli cell is vague in outline and is but faintly acidophilic. Cell membranes can be distinguished only at the base of the cell. The apex of the cell apparently consists of diffuse cytoplasm without a definite cell membrane. The Sertoli cell is structurally quite unlike any spermatogenic cell in the testis tubule. The interstitial cells are normal in character and number. This condition is found after irradiation of the testes and in cryptorchid testes of late adolescents. The author was unable to elicit any pertinent causative history in the series, however.

No history of cryptorchidism, radiation, continued febrile disease or of industrial experience which might be a contributing factor was found in these cases. The authors describe germinal aplasia as a pathological condition in otherwise healthy young men which was little known previously. Since the tubules are denuded of even the spermatogonia, these cases do not hold promise for any type of therapeutic management.

Another pathological condition of the testis is described which is characterized by tubules of normal size and configuration with normal spermatogonia and a great abundance of large primary spermatocytes, but no further stages in spermatogenesis. The large primary spermatocytes cannot be confused with any other cell in the tubule. They are the largest cell present, with distinct cytoplasm and a large nucleus. The chromatin of the nucleus in the usual resting stage is very distinct. In these cases spermatogenesis proceeds uniformly throughout spermatogonial division to the formation of the primary spermatocyte. These cells do not then divide again to form secondary spermatocytes; cell division is halted at this stage, and so the designation of spermatogenic arrest is made. Reduction division does not occur there are no secondary spermatocytes, and there is an abundance of cellular debris in the lumen of the tubule, which indicates that the primary spermatocyte failing to undergo reduction division, soon disintegrates. The testis of the hypophysectomized rat is quite similar to the testis found in the cases described and designated as spermatogenic arrest. In the rat in which the pituitary gland is removed before sexual maturity the spermatogenic cells develop normally through the stage of the primary

spermatocyte and no further. Secondary spermatocytes are not formed. In the rat hypophysectomized after sexual maturity a regression of the epithelium of the seminiferous tubules occurs. All mature sperms and secondary spermatocytes disappear but mitotic activity continues in the primary spermatocytes. This condition in the rat is quite similar histologically to that seen in the cases of spermatogenic arrest in man. In these cases there was no evidence of hypopituitarism or hypothyroidism. Repair of this condition in the rat occurs promptly after the application of gonadotropic hormones. The author was unable to elicit evidence that the gonadotropic hormones which are available for clinical use repairs this type of testicular deficiency in man.

The effects of the removal of the hypophysis in the rhesus monkey are significantly different from those in the rat. In the monkey the atrophy of the testis after hypophysectomy is more extensive than in the rat. The seminiferous epithelium very largely disappears. Primary spermatocytes do not remain as in the rat. A few of the original spermatogenic and the Sertoli cells remain. This is the common condition seen in the testis of boys and young adolescents in whom other metabolic disturbances of hypopituitarism occur.

These three categories of testis pathology represent diverse histological states and exhibit azoospermia of gonadal origin, but there is no known therapeutic medium which will restore spermatogenesis in these testes.

Patients with oligospermia, with sperm counts ranging from very few sperms up to from 40 to 60 million are much more difficult to classify on a morphological basis. Some of the testes from these patients represent early stages of progressive tubular fibrosis in which many tubules are structurally normal, but in which the total sperm production is seriously reduced. The overall impression obtained from an examination of testis biopsies from cases with oligospermia is that there is a reduced rate of spermatogenesis. In any normal testis not all stages of spermatogenesis are usually found in every cross section of a tubule. One area will show the primary spermatocyte in preponderance. In a second area

the secondary spermatocyte will be most numerous while in a third maturing sperms will be enmeshed within the cytoplasm of the sustentacular Sertoli cells. The tubules of testes which produce a small number of sperms have all of the components of the normal testis. Each cell is represented in proper proportion, but all are apparently reduced in number. It must be stated that this is an impression because no counts or statistical evaluations have been made.

Even though there is an abundance of tubules with all stages of spermatogenesis the spermatids may not mature into spermatozoa. This transition from spermatid to spermatozoa is histologically speaking a process of eliminating excess cytoplasm. Other unknown metabolic processes occur during this ripening process. It does appear however that much of the maturational process must take place while the sperm cell is enmeshed within the cytoplasm of the Sertoli cell. This is the state in which most tubular spermatozoa are found in the normal testis. In the normal testis, free spermatozoa are rarely seen in the lumens of the tubule. In testis biopsies of patients with oligospermia, the spermatozoa frequently are found as free cells in the lumen of the tubule. The spermatozoa are apparently not undergoing the needed maturation within or in contact with the cytoplasm of the sustentacular cell of Sertoli. The causes for these various testis tubule disturbances are obscure although obesity and hypothyroidism associated with oligospermia, as well as parotitis with associated orchitis may be a contributing cause.

Histological evidence of inflammation and infection in the testis is not common and is rarely seen in the cases in which the primary complaint is infertility. Charny has described conditions resulting from toxic states, which do not have a characteristic pathology. Doubtless many toxins affect the cytological condition of the testis adversely, but it is exceedingly difficult to determine what such substances may be. Indeed surgical manipulation of the tissue and poor fixation of the biopsy cause much cellular distortion which might be interpreted as being due to some hypothetical noxious agent.

DAVID ROSENBLUM, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Ferrero C.: Jaffe-Lichtenstein's Disease, Cystic Osteofibromatosis (La maladie de Jaffe-Lichtenstein, ostéofibromatose kystique) *Presse méd.*, 947 55 143

In 1938, Lichtenstein described a polyostotic fibrous dysplasia consisting of a segmentary osteolytic process involving the diaphyses and metaphyses of the long bones. The disease begins in the medullary portion of the bone and extends by progressive erosion into the cortex. Cystic or vaguely defined lesions develop insidiously until claudication or spontaneous fracture occurs as the first clinical evidence of the disease. While the condition is more common in the first two decades of life, it is also occasionally observed in older subjects with a history of repeated fracture. Pain is present only following fracture or when the lesion causes compression of a nerve. Mobility is not affected and the joints are intact. The blood chemistry is normal except in extreme cases. Roentgen examination reveals bone cysts, and practically normal consolidation of fractures with occasional osteomalacic callus. The structure and shape of the long bones are changed. Processes of extension or partial regeneration may confuse the image.

The most frequent localizations are the neck of the femur, the tibia, cranium, pelvis, ribs, phalanges, vertebrae, scapula, clavicle, metacarpals, and other bones in the order given.

The enlarged medullary cavity surrounded by an attenuated cortex is filled with fibrous tissue. The medullary tissue is replaced by a fibroma with pale fusiform cells which become progressively immature toward the periphery. The fibroma invades the cortex by peripheral extension via the Haversian canals. Vascularization is poor and hemorrhagic foci are rarely encountered. The arterial changes resemble somewhat those seen in neurofibromatosis. There is no inflammatory reaction and no marked osteoclastic or features characteristic of Recklinghausen's osteitis. The disease progresses by stages, with remissions occasionally lasting for years, and as a rule, final stabilization. The general health is not affected and malignant degeneration is quite exceptional. The disease must be differentiated from Recklinghausen's generalized fibrous osteitis and xanthomatosis. Certain "formes frustes" of xanthomatosis are in reality Jaffe-Lichtenstein's disease.

Jaffe-Lichtenstein's disease is caused by a deficiency of the bone forming mesenchyme although some writers attribute the fibrous tissue to the terminal diarthral stage of xanthomatous morrhage, or a quiescent stage of parathyroid osteitis.

The author has observed an associated Albright's syndrome in some cases and attributes the bone

lesions to neurofibromatosis. Such an interpretation would explain the tumoral behavior of these lesions, the complex syndromes (Albright's syndrome) and the presence in 1 patient of Jaffe-Lichtenstein's disease plus the cardinal features of neurofibromatosis. Recent published cases would seem to support this theory. Also leontiasis ossea with "pagetoid" roentgenologic features and multiple bone cysts may be merely a craniofacial localization of this disease. Further histologic studies will be needed to prove the author's hypothesis that Jaffe-Lichtenstein's disease is merely a skeletal localization of neurofibromatosis.

EDITH SCHAMBER MOORE.

Agostier E., and Robbins, R.: The Changing Concept of Myeloma of Bone. *Am J M Sc.*, 1947 213 25

More than 1,000 cases of myeloma are reported in the literature and the authors add their 13 cases from Temple University Hospital only to discuss the change in concept of the disease which has developed in the past 10 years. The change in concept involves (1) a better understanding of the subtypes, (2) its complex cytogenesis (3) recently developed laboratory diagnostic procedures, and (4) the nature of bone demineralization which it induces.

Three subtypes must be recognized. The classical type occurs as multiple tumors arising in red marrow simultaneously or successively over several months. Seven of the 13 cases studied were of this type. Tumors arise anywhere where red marrow is found. They are found preponderantly in flat bones where such marrow is found. In the age group from 40 to 60 years, which is commonly affected. In the rare younger patient the long bones will be affected if the red marrow is still active there. The lytic action of the tumor on contiguous bone makes roentgen ray films of the flat bones often diagnostic. A second subtype is the so-called "solitary myeloma," which is first seen as a single focus and may remain as such for a variable length of time. Four cases first seen in the single focus stage became multiple within 9 months.

A third subtype is a myeloma so generalized that all red marrow seems simultaneously affected. This produces generalized demineralization of bone, and consequent changes in the blood. Two cases of this type in elderly persons were misdiagnosed by means of x-ray as senile, idiopathic osteoporosis. They both showed marrow replacement by tumor cells throughout the flat skeleton. All of these types may eventually produce extramedullary extensions or metastases. A soft tissue tumor morphologically indistinguishable from some of the marrow tumors is different clinically to such an extent that it is not included here.

The cytogenesis of myeloma is not well understood. The plasma cell myeloma is the most common but not the only type. If we accept the concept that all

marrow elements are of mesenchymal origin. Ewing's tumor might be classified in the myeloid group and certainly its clinical features are not too dissimilar. Its site of predilection is consistent with the distribution of red marrow in its age group. Aspirated sternal marrow has shown identical tumor plasma cells in patients whose tumors, when directly biopsied, showed myeloid types and in those whose tumors were of the plasma cell type. The concept of Lowen-haupt and others that the plasma cell type arises from the reticuloendothelial elements of marrow and spleen likens myeloma to a diffuse process such as leucemia. Many and various views are propounded on the cytogenesis of this disease.

The role of Bence Jones protein, not as commonly present as previously thought in the production of the frequently encountered renal insufficiency is dubious. Hyperglobulinemia is encountered and should be looked for as well as hypercalcemia. A marked anemia is often encountered and a nonspecific rise in the sedimentation rate. Needle biopsy of the single lesion can be done particularly when cortical destruction is marked and pathologic interpretation is not difficult.

Although spontaneous fracture of a flat bone is highly suggestive of myeloma, there is sufficient pain before the fracture occurs for earlier diagnosis of the disease. Thorough study of patients in this age group with localized flat bone or back pain would save considerable time and money. A diagnosis of idiopathic senile osteoporosis should not be accepted as proof of the absence of myeloma, but in the presence of flat bone pain, sternal puncture and other laboratory procedures should be used to confirm the diagnosis.

FRANCIS E. BRENNER, M.D.

Pontano, T.: Dorsal Kyphosis following Tetany (Il gibbo dorsale tetanico). *Riforma med.* 1947 61:1

The author briefly reviews the literature showing that the first case of dorsal kyphosis following tetany was reported in 1905 by Hautsch. He then presents 21 cases of his own which he observed during the year of 1942.

In 5 of his cases the kyphosis appeared between the fifteenth and twenty fifth days and in 16 cases between the first and twelfth days. The majority of his cases occurred in infants. In some cases the kyphosis remained while in others it was transitory in type. The kyphosis in some cases was so mild that it was asymptomatic and was found only on careful x ray study.

Pathological specimens were examined in 3 cases in 1 by the author. In none of them was there evidence of tuberculosis, toxemia or neurotrophic changes. In all of the cases the cause was found to be mechanical compression.

The cervical and lumbar vertebrae rarely become damaged because of their great mobility. Only the dorsal segment is injured because of the rigidity of this portion of the vertebral column. The area usually damaged is from the third to the sixth dorsal vertebra.

CARLO SCUDERI, M.D.

Valls, J. and Músculo, D. T.: Osteochondritis Dissecans of the Hip (Osteochondritis dissecans de la cadera). *Rev. As. med. argent.* 1947 61: 29

Valls and Músculo report 5 cases of osteochondritis dissecans of the hip. The first case was that of a 24 year old man with pain in the right hip for nearly 5 years. The pain was nonradiating, intermittent, and occurred especially after heavy exercising. Clinically a decrease of 2 cm. in the size of the thigh and a slight limp were noted. X rays disclosed a zone in the head of the femur which was the size of an almond and was separated from the rest of the epiphysis by a definite furrow. A fibrocartilaginous fragment was removed surgically. Two years later the patient showed no symptoms at all and no defect was noted in the femur roentgenologically.

In the second case that of a 17 year old boy there was a decrease in the diameter of the right thigh and right leg. On x ray examination the head of the femur appeared to be deformed with zones of variable density. Similar findings were disclosed in the third case that of a 27 year old man.

At surgical intervention in the fourth case a bone fragment was removed. Seven months later the patient appeared symptomless. The fifth case disclosed the typical appearance of the disease, but could not be followed up.

The authors discuss briefly the pathogenesis, clinical and radiological picture and treatment of the disease.

WILLIAM E. RICHARDS, M.D.

Sutro, C. J.: Prominent Inner Malleolus; A Cause of Painful and Enlarged Ankle Region. *Am. J. Roentg.* 1947 57: 472

An abnormal prominence of the inner malleolus of the tibia was noted in each of 10 soldiers who had complained of recurrent pain and swelling of a single ankle. The soldiers sought permission to wear low quarter instead of the high G.I. shoes. Clinical and roentgenological examinations were made of 100 ankles in 50 soldiers who had no obvious disturbances of the feet or ankles for purposes of comparison with the prominent and painful ankles in other soldiers. When lateral bowing of the distal third of the leg was present the outline of the inner malleolus appeared to be unduly prominent. When the contour of the leg was straight the projection of the inner malleolus was barely perceptible. In none of the 100 ankles was there any evidence of soft tissue thickening over the inner malleolus. An analysis of the roentgenograms indicated that the axis of the internal malleolus was approximately at 30 degrees to a perpendicular from the region of the articular surface of the distal end of the tibia. The width of the internal malleolus was commonly found to approximate $\frac{1}{4}$ of an inch.

Five of the 10 patients who had made requests to wear low-quarter shoes had suffered from a sprain or fracture of one ankle, 3 to 15 years prior to the first visit to the clinic. They complained of pain and swelling of a single ankle which was aggravated by the wearing of high shoes. In civilian life they had worn low-quarter shoes and had experienced only a

minimal degree of pain and swelling. No evidence of any subcutaneous burnae was found nor was there an unusual lateral bowing of the tibia. Each had 5 to 10 degrees of restriction in the range of active and passive dorsiflexion in the affected ankle. Roentgenograms disclosed irregularity in the contour of the affected inner malleolus as well as an enlargement of the part manifested by widths between $\frac{3}{16}$ and $\frac{1}{2}$ of an inch. The malleolar angle ranged from 30 to 35 degrees. Hooklike projections formed by periosteal proliferation in the region of the inner malleolus were present. In 1 of the 5 there was present in addition to the periosteal changes, a unilateral accessory bone (os subtibiale) over the tip of the affected malleolus.

In the remaining 5 patients, who did not experience any previous local trauma, roentgenographs revealed 3 patients with trapezoid configuration or lateral bowing of the distal portions of both tibiae. One patient had anomalous flat sessile mounds on the attenuated cortices of both inner malleoli. The remaining patient showed a trapezoid configuration of the distal end of one tibia. All 5 patients demonstrated just above average determinations roentgenographically for the malleolar angle and width. Subcutaneous soft tissue swellings were present only over the painful malleoli in each of these 5 patients and they formed a good part of the local prominence.

Low-quarter shoes were prescribed to lessen irritation to the prominence. This, in conjunction with hydrotherapy, infra red radiation and limitation of military duties, resulted in definite alleviation of pain and diminution in the size of the soft tissue swelling. In no instance was the intrinsic shape or contour of the inner malleolus modified by this treatment.

KENNETH H. SPOONER, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Lamphier, T. A., and Cushman, C.: Treatment of Chronic Osteomyelitis with Streptomycin. *N. England J. M.* 1947 36 318.

There is no doubt that penicillin helped to eradicate and localize bone infections in World War II. Bacteremia and septicemia were rare but many soldiers returned with mixed infections that did not respond to penicillin. According to Abraham and Chalm, gram-negative bacteria produce a penicillin inhibiting enzyme called penicillinase. The gram-negative bacteria found most frequently and considered responsible for delayed wound healing were *Pseudomonas aeruginosa*, *Proteus vulgaris*, and *Aerobacter aerogenes*.

Asochloramide, acriflavine, and Dakin's solution were of doubtful value. Careful removal of x-ray opaque and nonopaque foreign bodies or necrotic tissue is important.

Four patients who did not respond to treatment with penicillin, sulfonamides, local antiseptics, and radical sequestrectomy were chosen for streptomycin therapy. The cultured bacteria were studied for

streptomycin sensitivity in vitro. Three to four days after thorough wound debridement, gelatin or fibrin foam soaked in streptomycin was applied to the entire open wound. 150,000 units of streptomycin were used locally and 300,000 units were given intramuscularly every 3 hours. *Pseudomonas aeruginosa* was found highly resistant to streptomycin both in vitro and in vivo but preliminary treatment of the wound with 1 per cent acetic acid solution and subsequent careful irrigation with saline solution was successful in overcoming this obstacle.

Three patients were treated with combined local and intramuscular streptomycin and one was treated with local streptomycin alone. The results were gratifying. Skin grafting and secondary closure were made possible in a much shorter time. However, observation for a period of several years will be necessary to exclude possible recurrences (previously observed in cases considered cured?).

Pain from repeated injections of streptomycin was alleviated by the addition of procaine. No toxic reactions were observed in this series.

ARTHUR J. LEMER, M.D.

Bateman, J. E.: Management of Extensive Complicated Defects in the Long Bones. *Am. J. Surg.* 1947 73 433.

In the repair of bone defects several preliminary steps have to be taken into consideration.

In spite of very valuable chemotherapeutic agents no surgery should be done until 6 months have elapsed after the cessation of drainage from the area. The skin covering the bone defect must have a good blood supply and must not be adherent to the underlying bone structures. A plastic procedure may be necessary. The suture of severed nerves is often indicated before repair of the bone defect is undertaken. Early nerve suture is beneficial and is not likely to activate previous infection. The existing bone defect may allow end-to-end nerve suture. Transplantation of the nerve will often facilitate repair of the bone defect.

The author carried out experiments on beef bone grafts to determine the breaking point and resistance to torsion. He came to the conclusion that dual onlay bone grafts are the most resistant to breaking (100 lb.) and torsion. Their use in the repair of bone defects is recommended.

A brief analysis of different types and shapes of bone grafts is outlined. The repair of defects in individual tubular bones is discussed in some detail with the help of diagrams and roentgenograms.

GROSVOR I. RIZZO, M.D.

Gabrizio, A.: Indications and Limitations of Surgery in Ischemic Paralysis (Indicazioni e Limiti nella chirurgia delle paralisi ischemiche). *Chirurgia moderna*, 1946, 30 3.

The author discusses various forms of treatment which have been recommended for ischemic paralysis of the forearm. He reports 3 cases of his own giving the complete clinical details in each case.

In pronounced cases of ischemic paralysis he recommends aponeurotomy and eventual open reduction of the fracture with surgery of the nerves and vessels if indicated.

In mild cases of ischemic paralysis he recommends elastic traction and careful observation.

In old cases he recommends the detachment of the insertions of the muscles from the epitrochlear region and plastic lengthening of the flexor tendons of the hand.

CARLO SCUTSCHI M.D.

Jerre T. : A Modification of the Nicola Operation for Recurrent Dislocation of the Shoulder Joint
(Eine Modification der Nicola'schen Operationsmethode bei habitueller Schultergelenkluxation)
Acta chir. scand., 1947 95 :

Recurrent dislocation of the shoulder joint has been of great interest to surgeons. In addition to operative procedures different types of orthopedic appliances to prevent dislocation have been investigated. These appliances were designed to prevent the motions in the shoulder joint which might cause the humerus to dislocate. I.e. predominantly in abduction. Furthermore the appliances gave additional protection to the anterior aspect of the shoulder joint in the usual anterior shoulder dislocations. Yet the disabling factor associated with the use of appliances is striking and most likely this type of treatment has been completely abandoned except in cases in which a minor operation is contraindicated.

Numerous operative procedures have been described, several of which are of historical interest only. Different procedures were tried to prevent redislocation of the shoulder joint for example resection of the humeral head, arthrodesis of the shoulder joint, different types of capsulorrhaphy, deepening of the fossa glenoidalis, fixation of the humeral head to the acromion, the coracoid process, or the superior rim of the glenoid fossa by the use of wire, fascia lata, the long peroneus tendon, the long or short tendon of the biceps muscle, by elevation of the anterior rim of the glenoid fossa with the use of bone graft, os purum, or by elongation of the coracoid process. Also different muscle transplantations, suture of the labrum glenoidale, or suture of the capsule directly to the bony rim of the glenoid fossa (in which holes were drilled prior to the suture of the capsule) were tried. It is beyond the scope of this article to discuss in detail all the suggested operative procedures. A short description of the Nicola operation and its modifications will be given.

In 1927 Heymanowitsch described an operative procedure for the treatment of recurrent dislocation of the shoulder joint of which there were two modifications. In the first modification the long head of the biceps muscle is severed close to its origin. Then a canal is drilled into the lateral aspect of the humerus in an anterior inferior to posterior superior direction. The tendon is then threaded through the canal and fastened to the acromion process. In the second modification the long head of the biceps is dissected out. However the tendon is cut at the level of the

surgical neck. Then a canal is drilled into the humeral head in such a manner that its superior opening comes to lie close to the origin of the tendon and the proximal glenoid rim. The proximal portion of the tendon is then inserted into the proximal opening of the canal and pushed through the canal to emerge from its distal opening. It is then sutured to the distal end of the tendon.

In 1929 Nicola described an operation (without mentioning Heymanowitsch) which differed in only minor details from the second modification of the Heymanowitsch operation. Nicola also frees the long head of the biceps up to its origin and severs it 2.5 cm. distal to the transverse ligament (the transverse ligament extends from the greater to the lesser tubercle and bridges the intertubercular canal). Then a canal is drilled into the humeral head from a point just distal to the transverse ligament and in such direction that its proximal opening comes to the center of the humeral head. The proximal portion of the tendon is then guided through the canal from above downward and sutured to the distal end of the tendon. Then the proximal portion of the tendon is put under tension and sutured to the periosteum near the transverse ligament to eliminate tension on the suture line between the proximal and distal portion of the tendon. This procedure is often referred to as the Heymanowitsch-Nicola operation or as the Nicola operation. It is widely employed.

Wahl described a modification of this technique in 1931. The tendon of the long head of the biceps is dissected out and severed from 2 to 3 fingerbreadths distally to the greater tubercle. The distal portion of the tendon is then sutured to the periosteum within the intertubercular canal. A canal directed in a posteroinferior direction is drilled into the greater tubercle from the proximal portion of the intertubercular canal. The proximal portion of the tendon is threaded through the artificial canal, folded over the inferior bony rim and sutured to the adjacent structures.

In 1933 Hobart suggested a more anatomical course of the tendon through the humeral head with out any sharp angulation and trauma to the tendon lying between the humeral and the glenoid fossa.

In 1933 Roberts published another modification. In 1934 Nicola again mentioned his method of repair incidental to a re-evaluation of his procedure. In this description of the procedure he states that the canal is to be constructed in such a way that its distal opening is located from $\frac{1}{2}$ to $\frac{1}{4}$ inch distally to the edge of the articular cartilage of the humeral head.

In 1935 Hobart described a procedure in which two operations were combined. First the modification of the Nicola operation described by Hobart is used and this is followed by a Chairmont-Ehrlich muscle plastic operation.

In 1935 Rupp sutured the tendon to the periosteum of the intertubercular canal at the level of both tubercles.

In 1940 Janek described a method similar to the Roberts modification which had been used by Frey

ka since 1933. Frejka frees the tendon of the long head of the biceps. Then the intertubercular canal is deepened and extended proximally. The tendon is then placed into the long and deep channel short end distal to the intertubercular canal and also sutured to the periosteum. The bone chips which were procured by the deepening of the intertubercular canal are used to cover the tendon which lies in the depth of the canal. The following advantages as compared with the original procedure described by Nicola are cited by Frejka. Deepening the intertubercular canal is less difficult than drilling a canal through the humeral head. There is less damage to the articular cartilage. There is no need to open the capsule widely. The tendon of the long head of the biceps is not divided. Therefore there is no danger of tearing of the sutures and slipping of the proximal portion of the tendon out of the canal, which might occur in Nicola's procedure.

In 1941 Ahlberg published a method which was said to have been used by Kjell Bergman in 1934. The tendon of the long head of the biceps is freed and divided just distal to the greater tubercle. The distal portion of the tendon is sutured in the intertubercular canal under an elevated bone fragment. The proximal portion is placed medial to the lesser tubercle and sutured underneath a bone fragment raised in the lesser tubercle. Ahlberg considers the Kjell Bergman method a less drastic procedure. The division of the tendon which constitutes a drawback in the Nicola operation is decreased in this procedure because the tendon is fixed under a raised bone fragment.

In 1945 Camitz mentioned another modification. The tendon of the long head of the biceps is dissected free. With the use of a chisel a channel is constructed alongside and underneath the lesser tubercle and wide enough to allow the tendon to be placed into it. There the tendon is fastened with catgut and with one or two silk sutures. In his address at the meeting of the Swedish surgeons in 1945 Camitz stated that his method simply consists of freeing the long tendon of the biceps, after exposure of the joint, all the way up to its origin at the supraglenoid tuberosity and far enough down to allow the tendon to be pulled over the greater tubercle and fixed in a channel underneath the lesser tubercle.

In 1943 Stenport began to use the following method in the repair of recurrent anterior dislocations of the shoulder joint at the Institute for the Crippled at Helsingborg. The patient is given ether anesthesia and his arm is placed on a table at 90 degrees abduction. A pillow is placed underneath the shoulder. A skin incision is made from the acromioclavicular joint along the anterior border of the deltoid muscle distally for about 10 cm. The cephalic vein is located in the cleft between the anterior edge of the deltoid and the pectoralis major muscle. The deltoid muscle is retracted laterally and the pectoralis major and the cephalic vein are retracted medially. The intertubercular canal is located by rotation of the arm. The transverse ligament bridging

the intertubercular canal is cut and the underlying long tendon of the biceps is exposed. The tendon is dissected free up into the shoulder joint, which makes it necessary to cut into the joint capsule. The arm is rotated externally to bring the lesser tubercle and the medially adjacent structures into the operative field. The tendon of the subscapularis muscle is severed at its insertion on the lesser tubercle and on the uppermost portion of the crest of the lesser tubercle. (Portions of the subscapularis muscle are also directly inserted on the joint capsule.) With the use of a chisel, a channel is constructed just medial to the lesser tubercle. The tendon of the long head of the biceps is pulled out of the intertubercular canal and over the lesser tubercle and placed into the newly constructed channel medial to the lesser tubercle. The tendon is fastened to the bony walls with catgut and silk sutures. (In the more recent operations, bone chips which were procured by the construction of the channel were placed on top of the tendon to form a roof over it.) The previously cut tendon of the subscapularis muscle is resutured to the periosteum of the lesser tubercle. The anterior edge of the deltoid and the pectoralis major muscle were approximated with 3 or 5 catgut sutures. The skin is united with silk or cotton sutures. The arm is placed immediately in 90 degrees of abduction and approximately 30 degrees of flexion and maintained in this position in an abduction splint. The patient is allowed to become ambulatory after 3 days. The abduction splint is kept in position for 14 days (previously it was kept on much longer). Then the patient is allowed to use active motion and the treatment is completed by eventually adding passive motion, massage, and heat therapy.

Nicola's operation and its modifications are not based on any pathologic-anatomical considerations and have for their aim only the fixation of the humeral head to the glenoid fossa. It has been established that there is a specific pathologic-anatomical cause for the recurrent shoulder dislocations which differs from the cause of common traumatic dislocation of the shoulder joint. The first dislocation is the recurrent type of dislocation of the shoulder usually occurs in younger individuals, while the traumatic dislocation usually occurs in middle aged or older patients. The recurrent dislocation of the shoulder is very rarely associated with tear of the supraspinatus tendon or fracture of the greater tubercle which is often found in traumatic dislocation of the shoulder. Various authors have stressed those and many other differences between recurrent and traumatic dislocation of the shoulder joint. It was generally assumed that a traumatic dislocation of the shoulder becomes a recurrent type of dislocation because of a constitutional tendency, primary deformity of the humeral head, tear of the supraspinatus tendon and the subsequent loss of stability of the joint, or a congenital predisposition.

Bankhart emphasized in 1938 that the recurrent and the traumatic dislocations of the shoulder joint are two different diseases, each type with its particu-

lar pathologic-anatomic basis. According to Bankhart, extreme abduction causes traumatic dislocation of the shoulder joint. The proximal portion of the humerus is pushed against the acromion and the head is lifted over the inferior rim of the glenoid fossa and out of the joint by tearing the capsule in the same area. This tear readily heals and this is why a traumatic dislocation never turns into a recurrent type. The anterior recurrent dislocation of the shoulder joint is caused by trauma to the shoulder with a force directed in a posterior-anterior line. It is either a direct trauma to the shoulder joint or a force which is transmitted to the longitudinal axis of the humerus, for example, a fall on the slightly laterally and posteriorly deviated elbow. Such an injury pushes the humeral head anteriorly out of the joint, between the glenoid fossa and the labrum glenoidale which is torn loose from its bony insertion on the glenoid fossa. The labrum glenoidale, composed of cartilage does not tend to unite with the bony rim of the glenoid fossa and this is why this type of dislocation becomes a recurrent dislocation of the shoulder joint. Bankhart was able to demonstrate these lesions in 27 consecutive patients who were operated upon. Hybbinette also found almost similar lesions of the capsule and the labrum glenoidale in his cases, which he repaired following his own intra-articular procedure. Best and Inman operated in 10 cases and Watson Jones in 34 cases following Bankhart's procedure, and were able in all cases to confirm Bankhart's findings. Meyers published a series of 31 cases in which operation was done according to Bankhart's procedure or some modification of this method. In all these cases a tear of the labrum glenoidale or a tear of the capsule near the glenoid fossa was found. Watson Jones states, however that in order to discover the tear it is necessary to sever the coracoid process, to cut the tendon of the subscapularis muscle and to dissect it away from the capsule to open the joint capsule and to force the humeral head out of the joint by having an assistant apply traction to the arm. On the other hand Odgers and Hark were able to demonstrate the tear in only 3 of 12 operations. Magnuson contends that this lesion is of no importance and was able to find it in only a few cases. Whether the tear of the labrum glenoidale occurs only in a few cases of anterior recurrent dislocation of the shoulder joint or whether according to Watson Jones, it actually composes the essential anatomical defect is irrelevant if Nicola's operation or its modifications are used since this procedure, as previously mentioned does not aim to repair the anatomical defect but is solely concerned with fastening the humeral head to the glenoid fossa.

Since 1943, 9 cases of anterior recurrent dislocation of the shoulder joint were operated upon at the Institute for the Crippled in Helsingborg by the mentioned modification of Nicola's operation. A more detailed description of these cases is outlined.

Of all the 9 patients operated upon, 1 could not be located for follow up examination. One died of an intercurrent disease but showed a good reconstruc-

tion of the shoulder joint. This patient had no complaints prior to her death. The follow up period was short in 1 case but it lasted from 1 to 3 years in the rest of the cases. There were no recurrences. The periods of hospitalization and of inability to work after the operation were short as compared with other procedures used in the repair of recurrent dislocation of the shoulder joint. Persistent symptoms were absent or very slight.

By using the modification of the Nicola operation certain advantages were gained which may be summarized as follows:

- 1 The operative technique is less difficult.
- 2 The operation is a minor one and does not necessitate wide exposure of the joint.
- 3 There is no injury to the articular cartilage.
- 4 The tendon of the long head of the biceps is not divided.

5 Finally it should be emphasized that the tendon which is used to secure the humeral head in the glenoid fossa is fastened medially on the humeral head in this modification. This is important from the mechanical point of view a fact which among others was stressed by Kapel and Nicola.

The early results obtained by using the modification of the Nicola operation can be classified as very good. It is impossible to state whether the final results will be just as good since recurrences may occur very late. In comparing the results of the Nicola operation and its modifications with the Eden Hybbinette and Bankhart methods one finds that the end results are worse following Nicola's method. In 1934 Nicola himself reviewed 32 cases which he operated upon since 1928. Recurrence occurred in only 1 case and only once. In the same publication Nicola mentions the fact that he learned of 3 recurrences which occurred in patients who were operated on in accordance with his own method but by other surgeons. Two of these 3 patients were reoperated upon. It was found that in 1 case the canal through the head of the humerus was much too large which allowed the tendon to slide up and down, and eventually caused it to tear out. In the other case the canal was found to have been wrongly placed which caused the humeral head to be unfavorably fixed to the glenoid fossa. These recurrences were due to faulty technique rather than to inefficiency of the method of repair. Roberts, Burnet, Frejka and Camils also were able to show successful results with the various modifications of the Nicola operation. Ahlberg published 4 cases without recurrences in which operation was done by the Kjell Bergman modification. On the other hand Watson Jones reported that he operated upon 18 patients according to Nicola's method. There were recurrences in 5 of the cases. Hublin used the Heymannowitsch method in 9 cases. Recurrence occurred in 3 cases 3 years after the operation, and after a reevaluation carried out at a later date it was found that all 7 patients who could be located had recurrences. Finally Thomason stated that 32 recurrences (14%) occurred in 225 patients (published in the

literature) who had been operated on by suspension methods.

The Eden-Hybbinette operation was very successful. Dahlgren published a series of 39 cases in which operation had been done according to the Eden-Hybbinette method. One patient died of pulmonary embolism, 2 patients never obtained full range of motion, 2 patients had recurrences after a bad trauma but there were no recurrent dislocations afterward. Spontaneous recurrences did not take place. Thomson who added 8 cases to the literature, which were operated on according to the same method without recurrence, gathered all the published cases which had been treated by different surgeons according to the Eden-Hybbinette method. He succeeded in collecting 169 cases which were treated according to this method, with only 1 spontaneous recurrence.

Bankhart's method of repair also has given very satisfactory results. Bankhart himself reported a series of 27 consecutive cases without recurrence. Watson-Jones, 34 cases without recurrence. Odgers and Hark, 12 cases without recurrence. Boat and Inman, 10 cases with 1 recurrence in an epileptic, and Meyers, 31 cases treated by Bankhart's method or one of its modifications without recurrence.

The results of the operations of Eden Hybbinette and Bankhart are very satisfactory as far as the number of recurrences are concerned and the results were better than those obtained with Nicola's method. The fact that the severed tendon is a weak point in Nicola's method is clear, this being stressed, among others by Watson-Jones and Frejka. Frejka states: "If the periosteal suture of the tendon relaxes, not only is the tendon itself weakened but also fastening of the shoulder joint is not achieved." In Watson-Jones' series of 18 cases treated in accordance with Nicola's operation not less than 5 recurrences occurred. Among those 4 were reoperated upon following another method. It was found that the tendon was torn in every one of these cases. Hublin reports that in 1 patient who had a recurrence after a Heymanowitch operation the tendon also was found torn but in addition it was found atrophied and stretched to such a degree that it was unable to give even the least amount of fixation of the humeral head to the glenoid fossa. Frejka, Roberts and Camits modifications do not require division of the tendon. Roberts operated in 2 cases using his own modification without recurrence. Frejka operated in 5 cases with 1 recurrence. Camits reported a series of 13 cases. He stated that in 1940 he began using his new modification without division of the tendon of the long head of the biceps. He operated in 10 cases since 1940. One patient had 2 recurrences.

The modification of the Nicola operation used at the Institute for the Crippled in Helsingborg has some advantages as compared with the original Nicola operation. This operation is preferable to the Eden Hybbinette and Bankhart operations because the procedure is less severe, the technique less difficult and the hospitalization and loss of working

time much shorter. Even if some recurrences take place at a later date, there is the advantage that a great number of patients are cured by a minor and technically easier operation. There was no need to subject them to the major operation of Eden-Hybbinette or of Bankhart with its associated dangers. Due to the less extensive operation on the shoulder joint and its surrounding structures a possible second operation because of recurrence is not made too difficult. However, this would be the case if the Eden-Hybbinette or Bankhart operation had been used.

In the summary the author describes a modification of the Nicola operation for anterior recurrent dislocation of the shoulder joint which Stenport started to use at the Institute for the Crippled in Helsingborg in 1943. On the whole 9 patients were operated upon according to this method. One of them could not be traced for re-examination. There were no recurrences. This method is recommended as it is a minor procedure, the technique is simple, the periods of hospitalization and inability to work are of short duration, and, eventually there are very minor residual complaints or none at all.

GEORGE I. RUM, M.D.

De Marchi, E.: Contribution to the Surgical Treatment of Painful Sacralization of the Lumbar Spine. (Contributo al trattamento chirurgico della sacralizzazione dolorosa della V lombare). *Chir. org. movim.* 1946, no. 438.

According to popular opinion sacralization of the fifth lumbar vertebra serves as a mechanical factor which is responsible for pressure on the nerve trunks; hence the conclusion that removal of the apophysis is indicated to relieve pain. The author disagrees with this concept and recommends apophysectomy of the fifth lumbar vertebra only after all conservative methods have failed. The main indication for the operation is a definitely identified sacroapophyseal arthrosis, especially if it is associated with a persistent deviation of the spine. The surgical intervention causes a considerable trauma and is not without danger. A coexistence of other pathologic lesions such as vertebral arthrosis or interapophyseal arthrosis must be excluded before operation is advised. Radicular symptoms may be due not to sacralization but to a concomitant hernia of an intervertebral disc; therefore myelography should be employed in every case to exclude the presence of such lesions.

The author reports 7 cases in which apophysectomy was performed with good results.

JOSEPH K. NARAY, M.D.

FRACTURES AND DISLOCATIONS

Lingley, J. R., and Robbins, L. L.: Fractures following Electroshock Therapy. *Radiology* 1947, 54: 48.

Since 1935 when Sakel in Vienna first reported insulin shock therapy for psychotics, methods of producing shock have been expanded and their use has

rapidly increased. Concurrently complications following and contraindications to shock therapy have been reported. In 1939 Polatin reported 51 cases of compression fracture of the thoracic vertebrae after metrazol treatment at the New York State Psychiatric Institute. This was a 43.2 per cent incidence most cases showing multiple fractures of from 1 to 8 thoracic vertebrae. Fracture of the pelvis, acetabulum, humerus, clavicle and scapula as well as dislocation of the jaw has been observed. The most frequent lesion is fracture of the spinal column usually the thoracic portion.

Many methods for the prevention of such trauma have been resorted to including mechanical restraint, no restraint, and the use of spinal anesthesia and drugs such as curare. No method has yet proved completely successful. In spite of contradictory reports, the consensus of opinion appears to be that spinal fractures except for pain are relatively insignificant. Fractures of the long bones or of the pelvis are more serious complications. Since some of the femoral fractures are subcapital, talipes or patients having had previous irradiation of the femoral neck area should probably not receive shock therapy.

Easton and Sommers reviewed 800 cases treated by shock therapy to compare the incidence of fracture in those given pre-shock curare and those not so prepared. Of the entire group of patients 26.1 per cent incurred vertebral fractures and of the 275 who received curare 5.8 per cent had fractures of the spine. The highest incidence of fracture occurred in patients under 25 years of age which substantiated Blumenthal's assertion that the muscularity of the patient plays an important role in the causation of fractures. The fourth, fifth and sixth thoracic vertebrae were most frequently affected. Patients whose bones appeared osteoporotic before treatment had an incidence of fracture which was double that of those whose bone density was roentgenographically normal.

The authors' study was carried out at McLean Hospital, Waverly, Massachusetts from September 1940 through February 1946. In this period 230 patients received electroshock therapy ranging from one treatment to several series of treatments. The electric current was calculated to produce a convulsion of 45 seconds duration. Five trained attendants held the patient just enough to prevent sudden hyperflexion and to absorb the initial shock of the convulsion. Routine x rays of the thoracic and lumbar spine were taken before therapy and afterward if the patient complained of pain or had any objective findings suggestive of fracture.

Of the 230 patients studied 53, or 23 per cent sustained fracture of one or more bones including 110 vertebrae. The incidence of fracture was greater in males than in females, and in the young and the old rather than in the middle-aged.

Regardless of the method by which the convulsion is produced it would seem that its severity is a great factor in the number of fractures incurred as well as in their location. Certain pre-existing conditions of bone notably osteoporosis and malignancy ap-

pear to contraindicate shock therapy as they render bone much more susceptible to fracture.

FRANCES E. BRENNEMER, M.D.

Masern, L. The Histopathological Aspects of Koehler's Disease of the Metatarsal Bones (Sul quadro istopatologico della malattia metatarsale di Koehler). *Chir. org. movim.* 1946 30 302.

The author reports 2 personal cases of Koehler's disease in which the involved metatarsal bone was resected and studied. Numerous previous reports on the microscopic pathology have been presented in the past. The author believes that the differences are based purely on the stages of the disease at the time it was studied.

It is the author's opinion that the changes in the metatarsal heads are explainable on the basis of nutritional disturbance of the bone. In the pathological specimens there is edema of the tissues later followed by necrosis of the bone and cartilage. Impaired circulation due to trauma is probably the cause of the condition in most cases.

CARLO SCUDERI, M.D.

ORTHOPEDICS IN GENERAL

Bennett, R. L.: Convalescent Care of the Weak-ened Shoulder with Particular Reference to the Use of the Overhead Sling. *South. M. J.* 1947 40 120.

Weakness of the muscles of the shoulder girdle results from central and peripheral nerve lesions as well as traumatic lesions about the shoulder that result in disuse and limited mobility. Among the causes of muscular weakness are acute anterior poliomyelitis, polyneuropathy, Erb's palsy, brachial plexus injuries and other purely motor nerve conditions, fractures, dislocations, contusions, sprains, neuritis, tendonitis, fibrositis, the scalenus anticus syndrome and other local bony and soft tissue lesions.

Functional capacity depends upon 3 factors, namely range of motion, muscle group strength and coordination of muscle action. The articulations must have a free and painless range of motion.

Efforts to restore or maintain a functional range of motion to the shoulder must be started just as soon as the medical condition of the patient permits. At first all mobilization should be passive and as painless as possible. In repose the patient should rest on his back with a pillow holding the arm at about 40 degrees from the body, the elbow semiflexed and the forearm supinated.

As the acute phase subsides the patient is placed in a sitting position with the shoulder protected by a sling or by resting the extremity on a padded bed table. Recovery can be limited just as much by a persistently elevated position as by the unsupported weight of the arm.

As the convalescent phase gets under way a combination of passive and active assistive motion is started. This should be supervised by a trained physical therapist during 4 or 5 periods each day. Massive motion is given for 4 distinct reasons: (1) to

maintain or restore a normal range of motion in the shoulder girdle (2) to assist circulation (3) to maintain patient awareness of normal position and (4) to stimulate flexion and extension reflexes in the muscles making up the shoulder girdle.

The author has designed a special type of shoulder sling to aid in active assistive muscle re-education. This consists of a leather band attached to an ordinary screen door spring which hangs from a rigid right angled support made of a metal rod (3/4 inch), attached to the chair. With the elbow forearm and wrist supported in this apparatus at the desired height the patient is encouraged to carry out routine activities which should be supervised. Muscle re-education should also be carried out in the therapeutic pool. The shoulder ladder shoulder wheel, and overhead pulleys should be used to assist and encourage the use of the shoulder. Specially adapted looms and other forms of occupational therapy care fully supervised aid in the convalescence.

DANIEL H. LEVITZAL, M.D.

Loebard, P. The Syndrome of Post traumatic Muscular Hypertonia and Degenerative Neuritis. Volkmann's Syndrome (Le syndrome post-traumatique d'hypertonie musculaire et de démyélinisation nerveuse. Syndrome de Volkmann) *Rev. orthop. Par.* 946 3 35

In this article Volkmann's syndrome is discussed in the light of newly acquired knowledge regarding the tone of the striated muscles, their central origin, and also in the light of Barré's work which emphasizes the reactions in the spinal cord elicited by the injured extremities. Injuries have been considered to be strictly localized disorders. Leriche has described vasomotor sequelae caused by injuries and predicted their effects on the spinal cord. Barré proved Leriche's predictions to be correct.

The influences of fractures on the spinal cord have been described in detail, as well as the associated symptoms which often are overlooked. Pain is transmitted to the cerebral cortex and stimuli are sent peripherally by way of the sympathetics which cause vascular reactions differing in each individual. Some suffer a transitory functional general paraplegia which cannot be based simply on pain and disruption of the continuity in an extremity because it never occurs in classical fractures however it does occur in certain cases of soft tissue injuries. The real reason for the loss of motor power is the loss of the balance of muscular tone the disturbed balance of the antagonists and synergists. Muscle tone depends on neuromuscular fibrils located in the muscle substance, aponeuroses, tendons, synovium and peritendium.

These stimuli are transmitted not only to the motor neurons but also to centers located in the medulla oblongata, cerebellum and cerebrum. The neuromuscular fibrils form a fundamental part in the reflex arc the myotatic reflex of Laddell and Sherrington, which postulates that each passive stretching of a muscular fiber is followed by an immediate and vigorous contraction. Passive extension of a paralyzed

or anesthetized muscle increases its tension by only a few grams. A muscle provided with all its necessary innervation is able to maintain a tension of several kilos. The contraction of the passively extended muscle persists or decreases very slightly as long as the passive extension of the muscle is maintained. This reflex is a localized process and is part of the spinal reflex; it does not radiate to the adjacent muscles. In case of a fracture the muscle tone is disturbed because the muscles are kept in extension by the hematoma, by the angulation of the fragments, or by the forceful stretching at the time of the accident. The result is contracture of certain muscles.

The myotatic reflex is responsible for the difficulties often encountered in the reduction of fractures. General anesthesia is not sufficient to abolish this reflex. Local anesthesia is the best way of suppressing it. Many investigators have demonstrated that infiltration of muscle tissue with novocaine electrically paralyzes the receptors for the myotatic reflex and abolishes voluntary contractions and non-tonic reflexes. Spinal anesthesia works even better since it has an effect which is similar to sectioning of the posterior roots.

Following the first hours of hypertonia a state of hypotonia ensues when the muscle loses its volume, shape and power. Leriche and Albert have pointed out that every trauma is first a trauma of the vasomotor system. There always is also a reaction of the spinal cord. These processes are not confined to a single axis but affect the corresponding sympathetic centers and travel up and down the gray matter secondarily affecting the opposite leg or all four extremities. Every fracture therefore acts upon all of the nerve centers particularly the spinal cord and the motor and sympathetic centers, then it affects sensation and eventually the cerebral cortex.

A 12 year old female sustained a fracture of the humerus and showed a fully developed paralysis of the three nerves and a Volkmann type deformity of the arm. There was complete loss of sensation from the finger tips to the radiocarpal joint line. The fingers were cold and cyanotic. There was edema of the skin extending up to the midforearm. Novocaine was injected into the flexors and pronators near their origin and the musculotendinous junction. A few minutes later the contracture disappeared and less than half an hour later the wrist and fingers could be supinated and hyperextended. The corrected position was maintained by an appliance. Ten weeks later sensation began to reappear on the dorsal aspect of the hand. The forced pronation of the arm caused a disturbance of the muscle tone resulting in hypertonia which was eliminated by procaine infiltration in a few minutes.

In the light of these considerations Volkmann's syndrome has the following underlying symptoms:

Vascular spasm is undoubtedly present and is located high in the brachial artery. From this level it very often descends distally. It has been shown experimentally that the reflex causing the spasm passes through the spinal cord.

2 The examination of the musculature shows three different phenomena which are worth discussing. Muscles supplied by the radial nerve show hypotonia even after function of the radial nerve has returned. The author compares these findings with similar signs observed in lead poisoning. In the regions of the flexor and pronator muscles two reactions occur which cause the changes in these muscles. Injury to the motor nerves causes paralysis of this muscle group and at the height of this change a quantity of acetylcholine is liberated which acts on the sick fibers and causes hypertonia of these muscles. The neuromuscular manifestations are not of secondary but of primary importance in the causation of Volkmann's syndrome and the central origin of this condition cannot be ruled out. In severe cases there is always atrophy of the muscles in the hand especially of the interosseous group. There is always a sensory factor superimposed on the motor factor in the region of the hand. Although the motor paralysis of the hand never improves sensation usually returns completely to the hand.

Arterial spasm although prolonged, cannot explain the symptoms of degeneration of the nerves. The paralysis encountered in Volkmann's contracture is not of a peripheral type. In view of the changes in the hand the similarity to the Aran Duchenne syndrome which indicates anterior poliomyelitis is significant. There are cases of the Aran Duchenne syndrome which are due to the action of lead on the anterior horn cells of the spinal cord. It is suggested that the cause of Volkmann's syndrome might be found in the spinal cord. GROSSER L. REISS, M.D.

Pisani A. J.: Pathognomonic Sign for Cyst of the Knee Cartilage. *Arch. Surg.*, 1927 54 138.

The author has studied 31 cases of cyst of the semilunar cartilage of the knee either medial or lateral and has found that in all cases the cystic

mass was prominent on extension of the knee and disappeared on acute flexion.

VERNON C. TURNER, M.D.

Morandi, G.: Oscillometric Studies of Amputation Stumps (*Ricerche oscillometriche nei monconi d'amputazione*). *Chir. org. movim.* 1946, 30 389.

Of 17,074 amputation stumps observed by the author 441 (2.57%) were on the upper extremity and 1,333 (7.72%) on the lower extremity. Of the 441 stumps of the upper extremity, 280 (63.50%) were on the forearm and 161 (36.50%) on the upper arm. Of 1,333 stumps of the lower extremities 661 (72.09%) were on the lower leg and 372 (27.90%) on the thigh.

Of 300 patients selected for oscillometric studies 52 had undergone amputation because of a grave injury 103 because of infected wounds and 145 because of frozen extremities.

Oscillometric studies on the amputation stumps showed that the method allows a clinical observation of regressive lesions of the arteries in the stump. Quantitative as well as qualitative alterations of the oscillometric curves may be found, the curves may assume a flat shape and the diastolic excursions may be augmented.

Toxic infectious processes aggravate the anatomic changes in the involved artery not only in the stump but in the proximal, higher located segments.

Frostbite markedly diminishes the oscillations which may reach the zero level. Not only hemodynamic factors i.e. a diminished blood flow, but also lesions of the vascular wall caused by toxic infectious processes or congelation are responsible for the changes in oscillometric curves in amputation stumps. Muscular atrophy in the stump impairs the propulsive effect of the muscles on the blood and thus contributes to changes in oscillometric curves.

JOSEPH K. NARAT, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Ventura, R.: A Rare Lesion from a Flare Gun (Su un singolare caso di lesione da razzo) *Arch. Ital. Chir.* 1946 68 400

The author's patient accidentally shot himself in the left thigh with a flare gun, burning the tissues and producing hemorrhage. The extremity was cold, the popliteal pulsation was weak, and the dorsal pedal artery was not palpable. The wound was debrided under local anesthesia by means of a nerve block. On extension of the incision to the apex of Scarpa's triangle, there was a sudden gush of blood from a defect in the femoral artery which was controlled by means of a fine silk suture impregnated with oiled vaseline. Muscle was sutured over the vessel, and a sulfonamide was used locally. Several days later the patient developed a fever showing evidence of infection in the wound. The wound was drained, only to start bleeding again. It was then reopened and the bleeding point of the femoral artery was ligated with catgut. Several days later hemorrhage recurred and ligation was again carried out.

The probable cause of secondary hemorrhage in this case may have been necrosis of the area from the ligatures, or an injury about the artery and its wall from the heat, which resulted in an aneurysm due to the intra-arterial pressure and finally rupture of the aneurysm.

Whenever possible suture of a blood vessel should be done instead of ligation, for pressure is greater in a ligated vessel than in a vessel with continuity.

ARTHUR F. CROSSLAND, M.D.

Freeman, N. E., and Storck, A. H.: Successful Suture of the Abdominal Aorta for Arteriovenous Fistula. *Surgery* 1947 63.

Arteriovenous fistula involving the abdominal aorta and vena cava is rare since patients generally succumb to the initial massive hemorrhage. If the patient recovers from the initial loss of blood, the short circuiting immediately places such a strain on the heart that early cardiac failure occurs. The first successful repair of such a fistula was recently reported by Pemberton et al (*Ann. Surg.* 1946 3:580). Freeman and Storck report a second case with a successful operative repair.

The patient received a perforating wound from a .25 caliber bullet which entered the abdomen 3 inches below the ensiform cartilage just to the right of the midline and emerged through the back at the level of the second lumbar vertebra. He was immediately paralyzed below the waist. On the day of injury a laparotomy was performed and 14 days later a laminectomy was done. Following the second operation there was considerable return of function in the lower extremities.

A pulsating mass with intense thrill was discovered in the upper abdomen 6 weeks after the original injury. Some dilated veins over the abdominal wall were observed. The heart was not enlarged although the pulse rate was 96. The blood pressure was 152/96. The lungs were clear and the liver normal in size.

Four months after the original injury there was a sudden increase in the size of the mass associated with abdominal discomfort and vomiting, and the thrill became more apparent. Accordingly operation was undertaken 12 days later.

A transperitoneal approach to the aneurysm through a right upper paramedian incision was attempted at first but was unsuccessful because of the presence of dilated veins over the anterior surface of the aorta. The peritoneum and transversalis fascia were then incised from within the abdomen just to the left of the midline to expose the anterior surface of the psoas muscle and the vertebral column. By the latter approach it was possible to place temporary tourniquets above and below the aneurysm as well as about the left renal artery. The aorta was cut away from the aneurysm. A large sac was found to intervene between the aorta and the vena cava. The opening in the aorta was closed by a transverse running stitch.

When the aorta was first occluded the blood pressure rose from 118/70 to 140/100 and the pulse went from 130 to 160. The tourniquet was left in place for 1 hour and 40 minutes. Upon release of the rubber tubing the systolic pressure dropped to 5, but within a half hour rose to 110/80. Postoperatively there was severe oliguria for almost a week and mild hypertension for a week, with retinal vasospasm. At the end of 8 months the patient showed no evidence of recurrence of the fistula.

The authors point out that the absence of cardiac hypertrophy in this case was probably the result of the position of a large aneurysmal sac between the compound vessels. The aneurysm lay behind the vena cava and so compressed it that the return flow of blood to the heart was hindered. The dilatation of the superficial veins over the abdomen was in keeping with that explanation.

THEODORE B. MARSHALL, M.D.

De Takata, G., and Reynolds, J. T.: The Surgical Treatment of Aneurysms of the Abdominal Aorta. *Surgery* 1947 2:443.

Although 500 cases of aneurysm of the abdominal aorta have been reported in the literature, only 30 of them have had surgical ligation, and of the 30 patients only 6 have survived the procedure for longer than a year. Wiring of abdominal aneurysms has been practiced for many years, but the authors noted a death in follow up material in the cases subjected to this technique. Aneurysmorrhaphy is

the third method reported useful in the treatment of these aneurysms

The authors report, in some detail 8 cases of aneurysm of the abdominal aorta 6 of which were subjected to surgical exploration. Of these 6 only 4 were deemed operable and 1 of these was wired the remaining 3 had bands of cellophane wrapped about the aorta proximal to the aneurysm and, in 1 case, the aneurysmal sac was reinforced with cellophane. Only the patients treated with cellophane banding survived for any length of time 1 living 14 months the second 8 months and the third 2 years.

The authors believe that cellophane banding is a most useful method of dealing with aneurysms in hypertensive and syphilitic groups as it provides a gradual occlusion by fibrosis stimulated by an ingredient in some types of cellophane

BLOOD TRANSFUSION

Hustin, A., and Rémy, R.: Influence of the Sex of the Donors and the Recipients on the Frequency and the Gravity of Transfusion Reactions (*Influence du sexe des donneurs et des récepteurs sur la fréquence et la gravité des incidents survenant au cours des transfusions sanguines*) *Presse méd.*, 1946, 54, 738.

A study of the reactions was made in 864 transfusions of citrated blood given at the Transfusion Center of the University Hospital in Brussels during the year 1942. There was a correlation of the incidence of reaction with the sex of the donor and recipient

There were reactions in 5.3 per cent of 206 cases in which both the donor and the recipient were males. When both the donor and recipient were females (202 cases) the reaction rate was 17.3 per cent. There were 219 transfusions in which the donor was male and the recipient female and 237 in which the donor was female and the recipient male. Reactions in these two groups occurred in 9.1 per cent and 6.3 per cent respectively.

Further analyses were made to determine the occurrence of the different types of reactions and the relation to the conditions for which the transfusions were given. The sex distribution of untoward reactions maintained essentially the same relative position in the more detailed analyses.

The authors conclude that the combination of female donor and female recipient is too hazardous.

Since the elimination of female donors is not feasible they conclude that the best procedure is to combine donors and recipients of opposite sexes.

THEODORE B. MARSHALL, M.D.

Zukerman, C. M.: Fatality in a Blood Donor. A Case Report with a Review of the Literature. *Ann. Int. M.* 1947, 26, 603.

The American Red Cross through its Blood Donor Center, collected approximately 13 million pints of blood during the period between 1941 and 1945. At the Chicago Blood Donor Center approximately 640,000 pints of blood were collected in the 3½ years of its operation. Despite careful checking and examination of donors there was one fatality in a blood donor. A white male following removal of 500 c.c. of blood, had a small watery emesis a few minutes after venesection. He was given 1/100 gr. of atropine sulfate. The blood pressure was 90/60, and the pulse was 78 per minute. He complained at the sudden onset of a slight substernal pressure without radiation gasped several times, and died. An autopsy was performed and the anatomic diagnosis was

Thrombotic occlusion of the right coronary artery marked coronary sclerosis with narrowing of both the left descending and the right coronary arteries focal fibrosis of posterior wall of right ventricle, edema of the lungs and acute passive congestion of the liver spleen, and kidneys.

Since a possible contributing factor in coronary occlusion may be the slowing of the systemic circulation, and since the coronary flow is regulated by the mean level of the arterial pressure, especially diastolic, any marked fall in blood pressure may act as a precipitating cause of coronary thrombosis. Approximately 6 per cent of the blood donors at the Chicago Blood Donor Center developed a systemic reaction varying from slight to marked pallor weakness faintness sweating nausea, and vomiting with a transient drop in blood pressure. In the presence of coronary sclerosis there is a tendency to hypersensitivity of the vagal type of carotid sinus reflex. Masters felt that regardless of whether coronary thrombosis took place on an arteriosclerotic basis, or as a result of hemorrhage into a plaque, it could be attributable to alterations in the coronary circulation.

A review of the literature reveals that the reported causes of death in blood donors were either air embolism or cardiovascular lesions such as coronary thrombosis, cerebral hemorrhage, or other arterial emboli.

LEROT J. KLEINSMAN, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE; POSTOPERATIVE TREATMENT

Harwood, H. B.: *Bronchoscopy in Postoperative Complications. Austral N Zealand J Surg* 947 16 1947

Many postoperative pulmonary complications follow bronchial obstruction and result in atelectasis or pneumonia. Such obstruction is usually due to a plug of mucus, but it is sometimes caused by a foreign body or an undiagnosed tumor. In cases in which the cough and laryngeal reflexes are depressed by lowered vitality or narcotics, the respiratory tract is more vulnerable and coughing may be incapable of clearing the bronchial tree. When patients are propped upright in bed they may become exhausted by unsuccessful efforts to cough sticky or copious sputum uphill; also pain in the wound on coughing or deep breathing may discourage efforts to clear the sputum. These complications may follow local as well as general anesthesia as their cause lies in the type of patient rather than the type of anesthesia.

At times urgent operations must be done in the presence of respiratory infections and occasionally operations of election may not be sufficiently long delayed after such infections. Some of the complications following such procedures may be avoided by immediate postoperative precautions. At the Royal Prince Alfred Hospital Sydney Australia, frequent sinus operations are performed on bronchiectatic patients under intratracheal ether anesthesia. In these cases bronchoscopic lavage is done on the day before operation and at the end of the procedure in this manner postoperative flare-ups and complications are prevented. The anesthetist can frequently prevent trouble by aspirating the pharynx and bronchial tree when he is aware of excess moisture in the respiratory tract.

The symptoms of retained bronchial secretions, which may come on suddenly are moist cough after expectoration, rales and rhonchi at the lung bases, progressive dyspnea, elevation of temperature, pulse, and respiration. Cyanosis may be present and occasionally there is pain in the chest. X-ray examinations may reveal hypoventilation, atelectasis or bronchial pneumonia. One should not be reluctant to move the patient for roentgenography as this movement may be sufficient to relieve the obstruction.

Most cases of obstruction will be cleared by deep breathing posturing, handclapping over the affected area, movement of the patient and the use of carbon dioxide. The use of morphine and wound support while the patient is encouraged to cough will help. If these conservative means fail, then bronchoscopic aspiration should be immediately considered. This procedure can be carried out in bed and in the ward. Premedication may be given and the procedure may be carried out under local anesthesia, obtained by

spraying the respiratory tract. The patient may be placed in semi Fowler position, or he may lie diagonally across the bed with the head to the right for the left lung and to the left for the right lung. After passage of the bronchoscope secretions are aspirated if these are sticky; lavage with 5 c.c. of saline is done. Relief is usually immediate and rarely has to be repeated.

If patients are not treated as indicated, lung abscess and bronchiectasis may develop. The author has seen this occur in a number of cases when persistent cough was not noted after postoperative pneumonia had subsided. He reports the case of one such patient who developed a sacular bronchiectasis and who is symptomatically improved by continued bronchoscopic lavage.

The author reports another case of a patient who developed bronchiectasis after a piece of rubber from a mouth gag lodged in the bronchus during operation. Four cases are reported of patients who made uneventful recoveries when these complications were recognized early and bronchoscopy was immediately instituted.

ROBERT MAYO TYKERT M.D.

Cummins, H. A Preliminary Note on a Study of Postoperative Thrombosis, with Special Reference to a Prethrombotic State. *Austral N Zealand J Surg* 1947 6:197

There is little doubt that the treatment of postoperative venous thrombosis with anticoagulants combined with surgical ligation in selected cases produces excellent results when the lesions are symptomatic; however investigation is now being directed toward criteria for recognition of the lesions before symptoms are produced. The history of previous attacks, familial incidence or varicose veins may be warning signs. Operations on the lower limbs and peritoneal cavity, long deep anesthesia and postoperative immobilization with the legs over pillows, all predispose to the complications. An unexplained elevation of the pulse or temperature are suspicious. The patient may complain of vague discomfort or pain in the thighs or calves for some time prior to the onset of thrombosis.

In the department of urology at the Royal Prince Alfred Hospital, Sydney Australia the author has carried out regular postoperative coagulation times on 80 patients undergoing major surgery. This investigation has largely substantiated Bergquist who suggested that a "prethrombotic state exists for some hours before the onset of signs or symptoms. Bergquist claimed that a coagulation time of around 3 minutes was characteristic. The author states that his present work suggests that the danger level may well be 4 minutes rather than 3 and he stresses that it is significant only when maintained at this level for several hours. Postoperative graphing of the reading was done

A total of 7 of the 80 patients studied had thrombotic incidents in all of these the "prethrombotic" period was quite distinct, and the patients were treated successfully with heparin. One other patient was presented who had a history of two previous thrombotic incidents and who developed a coagulation time of 3 minutes on the seventh postoperative day. This patient was treated with heparin the level returned to normal and no symptoms developed.

ROBERT MATO TERRY, M.D.

Portes, L., Varangot, J., and Vassy, S.: The Treatment of 50 Venous Thromboses in Women with Dicoumarol. End Results (Résultats obtenus par l'emploi de dicoumarol dans le traitement de 50 thromboses veineuses chez la femme). *Presse méd.* 1947 55 57

The pathogenesis of thrombosis has been a matter of controversy for many years. Today most authors agree that a dual mechanism, the action of a pathogenic organism or its toxin on the venous endothelium and a blood dyscrasia, are involved. In fact there is a reciprocal relationship between infection and the constitution of the blood. An example of this is the increased fibrinogen in pyrexias or following operation.

The majority of thromboses are classified between the extremes of strictly infectious and humoral. If one concedes that thrombosis is determined by upsetting the equilibrium between physiological coagulants and anticoagulants in the direction of hypercoagulation one must also concede that an upset in the opposite direction will prevent the occurrence and extension of a thrombosis. Two drugs, dicoumarol and heparin, have been shown to be therapeutically useful as anticoagulants. Dicoumarol is believed to delay coagulation by preventing the synthesis of prothrombin from vitamin K in the liver. Since there is no absolute correlation between the dosage of dicoumarol and the increase in prothrombin time, most authors advocate repeated determinations in regulating dosage. Since the action of dicoumarol occurs from 24 to 48 hours following its administration, heparin is added to it initially to counteract this delay. Following extensive animal experimentation the authors used the treatment clinically.

The authors agree with the English literature in that the systematic use of the drug for prophylaxis is to be condemned especially in preoperative or prepartum patients. They advocate use of the drug in cases of already established thrombosis to prevent extension and accelerate resorption by preventing further coagulation. To be successful adequate treatment must be started as soon as a thrombosis begins to develop.

In order for treatment to be effective, frequent prothrombin determinations should be done so that the level can be maintained between 20 and 40 per cent. This should be continued up to the eighth day following mobilization of the patient. While treatment must be adequate hemorrhages from the nose

gastrointestinal and genitourinary tracts or wound will result from too great a drop in the prothrombin level. One mild case occurred in the authors' series of 70 cases. It was treated with repeated whole blood transfusions.

In the usual plan of treatment an initial dose of 300 mgm. was given on the first day, then 200 mgm. on the second day and 100 mgm. on the third day. Daily prothrombin determinations were made. The desired level between 20 and 40 per cent was usually reached in 48 hours. When the prothrombin level reached 50 per cent which may occur between the fifth and ninth days, 300 mgm. of dicoumarol were given immediately and 200 mgm. on the following day. Finally if the prothrombin level reached 80 per cent, the initial dosages were repeated.

The criterion of cure adopted by the authors was the complete disappearance of edema as determined by comparative measurement of the two limbs at 6 fixed levels.

The insidious phlebitis cases were deliberately omitted from the series, as well as those cases in which the early initiation of the treatment aborted the phlebotic process. The authors then reported 50 cases of venous thromboses already established at the time treatment was instituted. 45 were cases of phlebitis and 5 of periphlebitis. Three of the patients had had emboli. In 2 the emboli occurred prior to the phlebitis and before treatment was begun. The third embolism (a mild case) occurred while the patient was under treatment. In this patient the desired decrease in prothrombin was never reached.

There were only insignificant sequelae in the patients seen after the phlebitis had completely subsided. In a few instances, a mild edema occurred at the end of the day. The late results were excellent. The average duration of the disease in the 50 cases was 183 days. No severe complications or fatalities attributable to the disease itself or to the treatment have been recorded by the authors.

GERARD GAGNON, M.D.

Evans, J. A. and Boller, R. J.: The Prevention of Postoperative Pulmonary Embolism. *N. Eng. J. Med.* 1947 236 392

During the past 8 years venous section and ligation and anticoagulant therapy by heparin or dicoumarol or a combination of these anticoagulants have been developed in the treatment of venous thrombosis and pulmonary embolism.

There are definite indications for both procedures. When laboratory and clinical experience in the use of dicoumarol is lacking femoral ligation is the method of choice.

At the Lahey Clinic femoral ligations are with few exceptions, limited to patients with venous thrombosis who must soon have a second stage operation to those with conditions such as hemorrhagic colitis, those with poor liver function and to those with ambulatory recurrence of phlebotrombosis with pulmonary embolism. If there is any venous thrombosis the present method of anticoagulant therapy is

to start immediately with both heparin, in Pitkin's menstruum and dicoumarol. A single dose of heparin prolongs the coagulation time before 2 hours have passed and protects the patient until a two-day latent period of dicoumarol action has elapsed by which time the prothrombin content has usually dropped. In the patient resistant to dicoumarol the injections of heparin are continued every second day.

Between January 1, 1945 and January 1, 1946 anticoagulant therapy was administered to 127 patients with postoperative venous thrombosis with or without benign pulmonary embolism, with death of only 2 patients. After January 1, 1946 another death occurred.

This record compares favorably with the results obtained by others with venous ligation and section for the prevention of pulmonary embolism.

Fifty-two sudden, unrecognized, or untreated fatal cases of pulmonary embolism occurring from 1940 to 1946 are analyzed. 48 of the fatalities occurred postoperatively. In 8 cases thrombosis and embolism had been recognized and the patient was treated. Two deaths occurred in patients with medical cardiac conditions, in one patient, preoperatively. Autopsy was performed in 21 cases.

Prophylactic exercises are suggested for the prevention of pulmonary embolism—such as wiggling of the feet a thousand times a day.

Death according to age and sex, was as follows: 17 patients were between the ages of 51 and 60 years, 14 were in the seventh and 1 were in the fifth decade. 33 of the patients were men and 19 were women. Twenty-seven patients had had surgery on the colon or in the pelvis, cranial operations had been performed in 3 cases, and splenectomy in 1 case.

Previous vein conditions may predispose to venous thrombosis.

In 25 patients the greatest liability to the first pulmonary embolism was from the sixth to the sixteenth postoperative day. In 11 patients, before the sixth day and in 12 after the sixteenth day.

The signs and symptoms frequently associated with pulmonary embolism are elevated temperature, circulatory collapse, dyspnea, tachycardia, cyanosis, and chest pain. Elevation of temperature and tachycardia are the more important warning signs.

Twenty-two patients died within an hour after the first symptoms, 20 died in from 2 to 24 hours, and 10 patients died more than 24 hours after the first signs of thrombosis and embolism. The courses of some of these cases are reviewed.

The authors state that routine postoperative examination of the legs for any evidence of phlebotrombosis should be carried out after all major surgical operations. This should consist of questioning the patient as to the presence of pain in legs, especially in the calf muscles. Even when a negative reply is given, the calf should be tested for tender ness, and an attempt made to elicit Homans' sign.

Forty-four of 52 patients gave warning of thrombotic processes, which means that in 85 per cent of the cases death from pulmonary embolism might

have been prevented if the warning signs had been appreciated and prophylactic measures undertaken.

GEORGE W. RICHARDSON, M.D.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Berman, J. K., Pierce, G. S., and Best, M. M.: Burn Shock: Its Treatment with Continuous Hypodermoclysis of Isotonic Solution of Sodium Chloride into the Burned Areas; Clinical Studies in 2 Cases. *Arch. Surg.* 946, 55-571.

The present paper is predicated on the experimental work of Berman, Peterson, and Butler reported in *Surgery Gynecology and Obstetrics* 1944, 78: 337-345 and the recent experience of applying these conclusions to two severely burned patients. The significant facts in the experimental work were that (1) there is a loss of water and electrolytes, chiefly salt, followed by plasma proteins into the burned area. (2) this loss continues until pressure in the tissue spaces equals the hydrostatic pressure in the capillaries, when reabsorption begins. (3) reabsorption occurs in a reverse manner, the lymphatics, behaving as semi-permeable membranes, return the colloids, then the capillaries absorb the crystalloids. (4) the loss of plasma occurs earlier in the more severe, than in the less severe burns. (5) treatment by hypodermoclysis of isotonic sodium chloride solution into the burned areas seems to decrease the amount of water and plasma lost and facilitates absorption of both. (6) it is thus an autotransfusion of lost colloids and crystalloids and in addition, is a method of supplying quickly the great demand for salt by injured tissues. (7) it makes possible the dilution and excretion of hypothetical toxins, helps to control body temperature, and prevents pulmonary edema and anuria. (8) human skin is not as loosely attached to the subcutaneous tissue as is that of the dog and therefore multiple injections would be necessary but the volume of solution would be less to produce intracellular pressure above that of effective capillary pressure.

The patients reported were severely burned following the explosion of a large tank filled with steaming hot sodium hydroxide. The burns were extensive involving 72 per cent and 71 per cent, respectively of the body surface and were second and third degree in type. Prior to hospitalization both of the patients had received 3/4 gr. of morphine sulfate subcutaneously and 500 c.c. of citrated blood plasma intravenously. Neither appeared to be in shock but because of pain apprehension and the complaint of severe coldness both patients were given morphine sulfate, 3/4 gr., intravenously. Isotonic sodium chloride solution was injected by hypodermoclysis into the burned areas by continuous drip. The needles were moved to various parts of the body. All burned areas being kept distended. The infusions were used continuously for 96 hours in amounts of 3,000 to 4,000 c.c. in 24 hours. Enteric coated sodium chloride tablets were given but were discontinued after

the first day because they caused nausea and vomiting. Tetanus antitoxin 1,500 units was administered and penicillin, 30,000 units was injected intramuscularly every 3 hours. A bland high protein diet, morphine for pain and enemas of isotonic salt solution as needed were ordered. 500 c.c. of whole blood were given each day for the first 3 days.

On the third day almost the entire subcutaneous space of the body, especially the trunk, was greatly distended with fluid. The infusions were discontinued on the fourth day. On the seventh day all areas were covered with dressings of isotonic sodium chloride solution and penicillin solution (200 units per cubic centimeter) except the fingers and toes which were separated with petrolatum gauze. The necrotic areas were loosened daily and this was facilitated by the infusions.

On the seventeenth day the first patient began to show a picture of sepsis and toxicity with laboratory results as follows: nonprotein nitrogen 28 mgm, carbon dioxide combining power 59.7 volumes per cent, plasma protein 4.65 gm., with 1.0 gm. albumin and 3.65 gm. globulin, a hematocrit reading of 43.5 volumes per cent, and leucocytes 16,350. Penicillin was increased to 50,000 units every 3 hours. Cold sponges of the face and anterior trunk were carried out frequently and the patient was placed in an oxygen tent. Delirium became worse, incontinence ensued and the patient refused food and water. Isotonic sodium chloride solution infusions were restarted and a transfusion of 1,000 c.c. of whole blood was given. The patient was transfused again on the thirty-fifth and thirty-eighth days. At this time the carbon dioxide combining power was 102. The wounds were clean, the entire back (the site of second degree burn) was healed, the face and neck had healed and the thighs, legs, and arms were healing rapidly. The urinary output was adequate: 1,500 c.c. with an intake of 3,500 c.c. and the urine was acid in spite of a carbon dioxide combining power of 114 volumes per cent. On the thirty-ninth day the patient was moribund, the nonprotein nitrogen was 26 mgm. the urine strongly alkaline, muscular twitchings were evident which later passed into clonic convulsions, respiration became labored, cyanosis developed, the patient lapsed into coma, and died the fortieth day after admission.

The significant findings at postmortem examination were as follows: "The peritoneal cavity contained about 100 c.c. of clear light yellow fluid, an equal amount of the same type of fluid was present in each side of the chest and about 35 c.c. were found in the pericardium. The cardiac muscle was edematous, with small scattered accumulations of lymphocytes. There was no pulmonary edema. The spleen was large weighing 240 gm. and engorged with blood. The liver showed extensive fatty infiltration and degeneration. Large areas showed total destruction of the parenchymal cells of the liver. The kidneys were swollen, and all their blood vessels were dilated and filled with red blood cells. The tubules contained refractile droplets as seen in nephrosis. Glomeruli

and Bowman's capsules showed little deviation from normal, however, the former were dilated and filled with red blood cells. The cerebrum was edematous. In some areas this was extreme. Here the blood vessels had shriveled and retracted and surrounding them there were small areas of advanced autolysis. Ganglion cells were pyknotic and degenerated in such areas. The cerebellum showed practically the same picture as the cerebrum. The adrenals contained areas of fatty degeneration and hemorrhagic extravasation chiefly in the medullary zone.

The pathologic diagnosis was (1) edema of the cardiac muscle and acute myocarditis, (2) acute peribronchiolar pneumonia, hemorrhagic phase, (3) fatty infiltration of the liver and toxic atrophy of the liver, (4) acute nephrosis and chronic passive congestion of the kidneys and (5) massive autolysis of the cerebrum with cerebral edema.

The second patient also had a turning point which occurred on the nineteenth day. His temperature rose to 103 F orally, he became confused, had hallucinations and illusions interspersed with periods of stupor. These were followed by generalized muscular twitchings which at times became gross tonic and clonic convulsions. There was some cyanosis and the patient refused food and water. Hypodermoclysis of normal saline solution was started again, 500 c.c. of whole blood was given. He was placed in an oxygen tent and given sodium amytal as required to control convulsions. Practically all second degree burns had healed and some third degree burns were ready for grafts. Open wounds were covered with packs of normal saline. An isotonic solution of sodium chloride was injected beneath the burns sufficient to cause slight weeping. This was done once a day. Sloughs were removed each day as they became loose and this was facilitated by the injections of the sodium chloride solution. On the twenty-ninth day the infusions were stopped. He was given a high protein regular diet and a vitamin B complex. He was able to sit on the edge of the bed on the thirty-seventh day and was discharged on the fifty-fifth day.

In view of the experimental work and the experience with these human cases the authors strongly recommend that the method be studied further in the human, that resistance to infection be increased, and healthy granulation tissue stimulated.

EDWIN W. PARABELLI, M.D.

Sulzberger, M. B., Kanof, A., and Baer, R. L.: Studies on the Acid Debridement of Burns. *Ann. Surg.* 1947 125 418.

It is generally agreed that the early removal of nonviable tissue or slough from third degree burns is desirable and that methods of removing the slough should be as gentle and nondamaging as possible as well as "selective" in that while nonviable tissue is removed all viable elements are left unharmed.

A study was devised to determine the most suitable methods of removing nonviable tissue from burned areas. Two symmetrically situated areas on the flexor surface of each forearm were burned in human

subjects. The burns were approximately 4 by 3 cm in size, and histologic examination showed the areas were largely third degree burns but occasionally islands of intact epithelial elements remained. The burns were produced by applying to the skin a round copper disc, 1 cm. in diameter and heated to a temperature of 67° C. for 60 seconds. The heat was kept constant by methanol heated to boiling in the bottom of the apparatus by a continuous electrical current. No pressure was used except that exerted by the weight of the applicator itself. Usually the debriding applications were begun on the third, fourth or fifth day after the receipt of the thermal burn. The medication used was applied in an identical manner. Approximately 10 c.c. of the medication tested were applied to one of the lesions and covered with a 3 by 3 in. square of gauze, which in turn was then covered by several layers of vaselined gauze. Over this dry elastoplast. The agent was applied daily or until further applications had to be discontinued because of a prohibitive degree of irritation. On the average, debridement took a total of 4 or 5 days for the burn. When the debriding agent was discontinued both cent sulfonamide cream which was applied daily until healing was complete.

The results indicated that 0.9 per cent of pyruvic acid starch paste was more effective than plain starch paste in producing complete and rapid slough removal and therefore, in accelerating healing. Treatment with pyruvic acid starch paste produced more rapid healing than leaving the lesions untreated, treatment under pressure bandage with 5 per cent sodium sulfadiazine cream, treatment with 5 per cent sulfadiazine cream or treatment with 5 per cent silver nitrate in petrolatum. The results obtained from treatment with other acids and gels indicate that the effects of acid debridement are not specific for pyruvic acid. Acid debridement appears to be dependent on the maintenance of the correct supply of hydrogen ions over a sufficient period of time. Among the other acids tested 0.1 molar phosphoric acid (which has a p_H of 2.0 and is a weakly dissociated acid) proved to be the best from all viewpoints. It was approximately as effective in slough removal and in accelerating healing as was 0.1 molar pyruvic acid and 0.1 molar phosphoric acid in methyl cellulose water gel or in K-Y jelly. It was demonstrated that certain forms of dry hygroscopic powders containing the acids could be prepared which on the addition of water would rapidly form suitable gels. These proved to be less friable and almost as effective as pyruvic acid starch paste in removing slough and promoting healing of chemical and thermal burns.

Sellers, E. A., and Best, C. H.: Effects of Diets on Nitrogen Loss in Urine after Burns. *Bull. N.Y.S.* 1947: 132.

After burns or other injuries the urinary excretion of nitrogen may be definitely increased. Previous

investigations have indicated that the extent and depth of burning affect the amount and type of nitrogenous material excreted. Large amounts of protein must be administered after extensive burns if nitrogen equilibrium is to be maintained. Croft and Peters reported that the increase in nitrogen loss after burning could be reduced substantially by giving methionine or a protein supplement, to rats maintained on a moderate or low protein diet. This observation has been checked by the present authors and confirmed only in part. Young female rats weighing between 100 and 150 gm. were placed on a diet of 15 gm. of fox chow a day until a moderately constant urinary output of nitrogen was secured. This usually occurred in from 10 to 14 days. Under ether anesthesia they were then subjected for a period of 30 seconds to water at 85° C. in order to produce a burn of the back amounting to about one third of the surface area. On the day of the burn and daily thereafter a buffered solution of methionine equal to 1 per cent of the diet was injected subcutaneously into 6 of the 9 rats used in the experiment. Urinary nitrogen estimations were made at 48 hour intervals for 10 days after the burning.

The following conclusions were drawn:

1. Methionine supplement (1%) to a stock diet did not reduce the urinary loss of nitrogen after burning.

2. When a methionine deficiency existed in the basal diet of young rats however a supplement of methionine lowered the nitrogen excretion. Cystine plus an adequate choline intake was ineffective in reducing the nitrogen loss in young rats.

3. A lysine supplement added to a lysine deficient diet was also ineffective.

The experimental basis for the use of methionine in the treatment of burns would therefore appear to be limited to the finding that methionine is effective in young animals receiving a diet very low in this amino acid. With a more extensive injury the beneficial effect of giving this amino acid to adult animals might be revealed.

Langlois, J. L., Owen, C. R., and Cope, O. I.: Bacteriologic Study of Burn Wounds. *Ann. Surg.* 1947: 545.

Flourishing contaminating bacteria in a burn wound are a deterrent to the healing of the wound. The control of these organisms has been attempted by many methods. Solvents such as Dakin's solution, coagulating chemicals, and the more selective vital dyes have been applied to the wound surface but in their toxicity to bacterial growth they have proved damaging to the viable cells. The sulfonamides applied locally do not damage viable cells, but as they are limited to antistreptococcal specificity they have failed to block the development of other bacterial species in the wound. Attempts to control less susceptible organisms by increasing the local concentration of sulfonamide are prohibited because of the rapid absorption of sulfonamide from the wound surface which causes a rise in concentration of the drug to toxic levels in the body fluids and renal

failure. Systemically administered sulfonamide has the same limit of toxicity and is successful in controlling only the invasive infection of the streptococcus. It was hoped that penicillin would succeed where the sulfonamides had failed because of its wider antibacterial properties and virtual lack of toxicity. Studies were devised to demonstrate the nature of the bacterial contamination found in partial and full thickness burns in patients treated with either penicillin or sulfadiazine.

On entry to the hospital each patient was placed in an isolated room where every precaution was taken to avoid further contamination. The burn wounds were then covered without débridement or cleansing with a dressing of petrolatum gauze, thick dry cotton and an elastic bandage or towel. Subsequent changes of dressing were made in an operating room under aseptic precautions. The burns were arbitrarily divided into areas or wounds, and cultures were taken of each wound on admission and at each subsequent change of dressing until healing occurred. Isolation and identification of all morphologic types seen microscopically was attempted. Fifty-four patients were observed under systemic penicillin therapy and 38 under systemic sulfadiazine therapy. No patients were observed for any length of time who did not receive either form of chemotherapy. The penicillin dosage was low in the first cases (100,000 units or less per day) and high in the later cases (from 250,000 to 500,000 units per day). The dosage of sulfadiazine was regulated by the blood level of the drug and was maintained between 6 and 12 mgm./per cent. Cultures were obtained once a week from nearly all of the wounds.

It was evident that neither sulfadiazine nor penicillin exerted more than a limited control over the growth of bacteria in the deep burn wound and the number of strains multiplied in the absence of chemotherapy. Multiplication did not occur with sulfadiazine therapy and the number of strains slowly decreased during penicillin therapy. Resistance to penicillin developed rapidly however and avirulent forms were replaced by virulent bacteria. No beta streptococci were recovered on the day of injury from the full thickness burn wounds of patients subsequently treated with penicillin. There was more prompt elimination of the beta hemolytic streptococcus by penicillin than by sulfadiazine from those wounds in which this organism was encountered. This was presumably due to the observed inability of the beta hemolytic streptococcus to develop resistance to penicillin. The alpha and gamma streptococci slowly disappeared from the wounds of patients treated with sulfadiazine. In the wounds of the penicillin treated patients, in contrast, these streptococci grew until by the eighth week 90 per cent of all the unhealed wounds contained an alpha strain and a majority of the remainder a gamma strain and a few contained both. These two streptococci were found to develop resistance to penicillin rapidly.

Wounds of the buttocks, thighs and legs showed the greatest contamination and the highest incidence

of clostridia and the gamma or fecal type of streptococcus. Wounds of the head and neck revealed the least contamination, with no gamma streptococci and but few clostridia. The degree of contamination of the wounds of the upper extremities lay midway between the degrees of contamination of the other two body areas. It is suggested that clostridial antitoxin be considered in addition to tetanus antitoxin and prompt excision of slough be done in the therapy of patients with full thickness wounds of the lower extremity.

The rapid development of resistance to penicillin by the previously sensitive staphylococci and streptococci and the profusion of penicillin inhibiting and insensitive gram negative bacilli indicate that the effective period of penicillin therapy is sharply limited to the first 3 weeks. Six weeks after injury the wounds have become a bacterial quagmire.

The infection of burns is a problem of deep burns. The fight against it combines prevention of contamination, starvation of the bacteria by prompt excision of slough, an attack with penicillin, streptomycin, and sulfadiazine, and bolstering of the immune processes of the host by restoration and maintenance of physiologic balance of the patient.

FRANK F. KANTHAKE, M.D.

North, J. P.: Clostridial Wound Infections and Gas Gangrene. *Surgery* 1947 21: 364.

This paper is based on the author's experience with clostridial wound infections treated in an Army hospital in the North Burma Theater. The loss of life and limb which results from delay in the correct diagnosis of this infection is a challenge which can be met only by maintaining a constant rather than a sporadic interest in this disease. The distinction should be clearly made between the more or less localized clostridial infections, which have an excellent prognosis with conservative surgical management, on the one hand, and a true gas gangrene, which is a diffuse disease carrying an immediate threat to life and urgently demanding radical surgery. The author emphasizes that the adequacy of the arterial circulation is the factor which determines which of these two types of clostridial infection will result.

The incidence of this infection during the first World War in wounds of the soft tissues was 10.8 per 1,000 cases, and in wounds with compound fractures 63 per 1,000 cases. While the final figures are not available for the incidence of this infection during the second World War, isolated reports from the various theaters show the incidence of infection in soft tissue wounds was 6 per 1,000 cases and in wounds with compound fractures, 17 per 1,000 cases.

If the principal arterial trunk of an injured extremity is intact, the clostridial infection may be expected to localize, and, conversely, in the presence of injury to the main arterial supply the clostridial infection may be diffuse and gas gangrene may result. In the author's cases, to his certain knowledge 73 per cent, and probably 100 per cent, of patients with gas gan-

grene had major vascular damage of the 37 patients with a localized clostridial infection, only 3 had vascular damage, and this was of limited extent. Thus, he believes that the degree of arterial damage is the determining factor in the course of the infection.

Early diagnosis will be facilitated if the surgeon is suspicious of any case which, from the history or physical findings, presents evidence of serious arterial damage. A history of sudden increase of pain in the wound is of the greatest importance; the pulse and temperature chart cannot be relied upon. Direct examination of the wound may show marked edema, tension, and crepitation. A thin serosanguineous discharge is usually present and a dead horse odor is very common and pronounced.

In this series there were 35 cases of gas gangrene with a 31.3 per cent mortality. There should be no delay in resorting to appropriate surgery and this implies amputation. Resection of muscle groups and more conservative surgical methods are of value only in the localized forms of the infection, and are of no value in stopping the spread of infection of the gangrenous type. The amputations should be done at the level of an adequate blood supply; this will not necessarily coincide with the upper limits of crepitation or infection, which may extend well beyond the limits of vascular damage. The amputation should always be of the guillotine type.

Blood transfusions and plasma are important adjuncts to surgery. Sulfonamides probably have no direct effect on the clostridial infection but should be used to reduce the synergistic organisms. The author does not believe that antitoxin is of any value, and could detect no difference between the cases in which it was used and those in which it was not used. He does not believe that he can evaluate the value of penicillin in this infection, but advocates its use.

F. J. LINDENBAUM, JR., M.D.

Meleney F. L., and Johnson, B. Bacitracin Therapy. *J. Am. Med. Ass.* 1947 33 675

In May, 1943 the authors isolated an aerobic gram-positive spore forming bacillus which was an antibiotic agent. The active principle was present in the filtrate of the bacterial culture and was named bacitracin.

The crude filtrate was found to inhibit the growth of hemolytic streptococci in the test tube and on blood agar plates. The crude filtrate also was found to have an abortive action on certain local human infections, such as furuncles and carbuncles, when injected into the center of the lesion.

Herbert Anker, biochemist, extracted the antibiotic from the crude filtrate with butyl alcohol and obtained a preparation in an aqueous solution. When this was dried an amorphous, slightly yellowish powder was obtained.

During the last 3 months a preparation which is highly soluble and of low toxicity has been made available.

The results of 90 surgical infections treated during the last 3 years are presented. The first 7 in-

fections were treated with the crude filtrate from the culture of the bacillus which produced the antibiotic, the next 30 infections were treated with the concentrated product prepared by Anker and the remaining 63 were treated with material furnished by Ben Venne Laboratories.

These cases represent the ordinary run of surgical infections. In many cases the lesion has been treated unsuccessfully with penicillin or sulfonamide drugs, the organism being found resistant or antagonistic.

Bacitracin was administered in two forms: (1) in an aqueous solution and (2) in a water soluble ointment base. Fifty-seven infections were treated with solution, 35 with ointment and 22 with both. Excellent results were obtained in 31 cases, good results in 57 and questionable results in 9; in 3 cases bacitracin was ineffective. Excellent results are those in which the infections treated with bacitracin responded within 72 hours. Illustrative cases in each group are reported.

Response to bacitracin was significant, with prompt subsidence of swelling, redness, and exudate, or the rapid resolution of the infection. All infections treated in the first 3 days showed a favorable response. The results were not entirely satisfactory in infections which had been present longer.

The unit has been established tentatively as that amount of bacitracin which can be diluted 1,024 times and still inhibit the growth of 0.1 c.c. of a 1 to 100 dilution of an 18 hour culture of stock strain of hemolytic streptococci (representing about 1 million organisms) when planted in 2 c.c. of culture medium.

The well known producers of penicillinase do not inactivate bacitracin and it is for that reason that the latter agent may be more effective in the treatment of mixed infections. The majority of infections treated showed a mixture of organisms. Only the coagulase positive staphylococci were present more often in pure than in mixed cultures. None of the gram negative aerobic bacilli that were tested were susceptible either to penicillin or bacitracin.

Bacitracin, like penicillin will often obviate the necessity for surgical procedure. Bacitracin is neither locally toxic nor irritating and is not inhibited by plasma, blood, pus or broken down tissue.

GEORGE W. RICHARDSON, M.D.

Anderson, A. B.: Anaphylactic Purpura following Intramuscular Penicillin Therapy. *Med. J. Australia*, 1947 1 303

The author gives an account of a case of anaphylaxis, apparently resulting from penicillin therapy, and manifested by transient swelling of joints and subcutaneous tissues, intestinal purpura, and toxic nephritis.

The patient was a 37 year old male who had no family history of purpura. He was admitted to the hospital for operation for an osteosarcoma of the lower end of the femur. On the nineteenth post-operative day there was purulent discharge from the wound. Penicillin therapy 15,000 units every 3 hours, was begun a total of 300,000 units being

given. The wound healed and the patient was discharged in 1 week.

About 6 weeks later during which interval the sinus reopened and closed several times, the patient slipped and fell. The fall was followed by an acute synovitis of the right knee joint necessitating readmission of the patient to the hospital. Culture of the wound discharge revealed *Staphylococcus aureus* and the patient was given 945,000 units of penicillin over a period of 9 days, at the end of which time the sinus had ceased draining.

Two days later he developed upper abdominal pain and tenderness associated with one emesis, followed in another 3 days by raised painful areas on the arms which subsided in 4 hours. The next day there was swelling of the metacarpophalangeal joints, severe abdominal pain, diarrhea and melena and ephedrine treatment was begun.

During the next 3 days the pain, melena and swelling of the hands persisted with the addition of hematemesis. The blood platelet count was 300,000 per cubic millimeter. Treatment consisted of adrenalin, "penta kaps" and glucose. The general condition of the patient then began to improve although urinalyses revealed albuminuria, numerous casts and red blood cells. There were no retinal changes or generalized edema. Blood pressure readings were normal.

This patient showed the joint symptoms described by Schönlein and the intestinal crises described by Henoch with a persistent associated toxic nephritis.

S. LEON TRETILMAN, M.D.

Rotman Kavka, G., Hirsch, H. L. and Dowling, H. F.: A Comparative Study of Penicillins X and G and Crystalline Penicillin G. *N. England J. M.* 1947 236-314.

Four different fractions obtained from penicillium notatum have been identified and named F, G, K, and X. Fractions G and X have received the greatest attention. It is known that commercial preparations contain different amounts of these fractions.

The purpose of the present study was to determine the respective potency of each fraction. Following the intramuscular injection of penicillin X, blood concentrations were higher and urinary excretions were present for 24 hours, as compared with 18 hours after the administration of penicillin G. No difference in effect was observed between commercial and crystalline penicillin. The relative sensitivity of bacterial strains to penicillin G and X was computed on the basis of weight and some minor differences were found. Therapeutically penicillin G and X appear to be about equally effective with two exceptions: (1) penicillin X may be given less frequently due to slower excretion and (2) very occasionally a bacterial organism may be resistant to penicillin G but sensitive to penicillin X.

Only 7 patients, among a total of over 450 showed toxic reactions. Most of these occurred with early impure preparations. 6 patients had urticaria and 1 patient had fever. The rash disappeared in 5 pa-

tients in spite of continuation of treatment and the sixth patient developed urticaria of short duration 7 days after the discontinuation of penicillin. No untoward reactions were observed after intrathecal injections of 100,000 units.

ARTHUR J. LEXER, M.D.

Pulszki E. J. and Amespacher W. H.: Streptomycin Therapy for Bacteremia. *Am. J. Surg.* 1947 73 347.

The authors state that with the successful treatment of hemolytic streptococcus septicemia by the use of sulfonamides, the modern era of effective control of infection by chemical and antibiotic substances was ushered in.

Since 1943 the superiority of penicillin over all other available forms of treatment for infections due to susceptible organisms has been clearly demonstrated.

There still remain a large group of microorganisms, notably the gram negative bacilli which are refractory to penicillin and which may on occasion invade the blood stream from a suppurating lesion.

Streptomycin is the most promising antibiotic aid presently available for the management of gram negative bacillary infections.

The present data reveal results better than those obtained with the use of the sulfonamides. The effects are more rapid, more certain and serious toxic reactions are fewer and less debilitating.

Streptomycin is bacteriostatic for gram-positive cocci as well as for gram negative bacilli but its action is not as powerful as that of penicillin on gram positive cocci; therefore it is an alternative agent for those cases not responding to penicillin therapy.

Data on 24 cases of bacteremia are reported. In the 16 cases of bacteremia due to gram negative bacilli, the urinary tract was involved in 11 cases, while in the remaining cases the infection arose from sepsis in bone and in the peritoneal cavity.

The majority of patients received 1 gm. or more of streptomycin in divided intramuscular doses, and treatment was continued for an average period of 14 days. Other chemotherapy failed in 14 of the 24 patients before streptomycin was employed. Twenty-two patients recovered and 2 died. In 18 of the 22 patients, beneficial results were attributed to streptomycin and in the remaining 4 patients the results were of questionable value.

In nearly every instance the temperature subsided by a step-ladder type of lysis. In most instances the blood was rapidly sterilized of the bacteria, with surgical drainage contributing to most rapid clearance of the blood stream. Occasionally reinfection occurred after withdrawal of the streptomycin.

Little evidence of improvement was noted until the third or fourth day. All patients who recovered were benefited by the seventh day. With urinary calculi the bacteremias cleared but the urine remained infected until the calculi were removed. In cases of bone lesions the infection was localized by streptomycin but surgery was necessary.

grena had major vascular damage of the 37 patients with a localized clostridial infection, only 3 had vascular damage, and this was of limited extent. Thus he believes that the degree of arterial damage is the determining factor in the course of the infection.

Early diagnosis will be facilitated if the surgeon is suspicious of any case which, from the history or physical findings, presents evidence of serious arterial damage. A history of sudden increase of pain in the wound is of the greatest importance; the pulse and temperature chart cannot be relied upon. Direct examination of the wound may show marked edema, tension, and crepitation. A thin serosanguineous discharge is usually present and a "dead house" odor is very common and pronounced.

In this series there were 33 cases of gas gangrene with a 31.3 per cent mortality. There should be no delay in resorting to appropriate surgery and this implies amputation. Resection of muscle groups and more conservative surgical methods are of value only in the localized forms of the infection, and are of no value in stopping the spread of infection of the gangrenous type. The amputations should be done at the level of an adequate blood supply; this will not necessarily coincide with the upper limits of crepitation or infection, which may extend well beyond the limits of vascular damage. The amputation should always be of the guillotine type.

Blood transfusions and plasma are important adjuncts to surgery. Sulfonamides probably have no direct effect on the clostridial infection but should be used to reduce the synergistic organisms. The author does not believe that antitoxin is of any value, and could detect no difference between the cases in which it was used and those in which it was not used. He does not believe that he can evaluate the value of penicillin in this infection, but advocates its use.

F. J. LEHMANN, JR., M.D.

Meleney, F. L., and Johnson, B.: Bacitracin Therapy. *J. Am. Med. Ass.* 1947, 33, 675.

In May, 1943 the authors isolated an aerobic gram-positive spore forming bacillus which was an antibiotic agent. The active principle was present in the filtrate of the bacterial culture and was named bacitracin.

The crude filtrate was found to inhibit the growth of hemolytic streptococci in the test tube and on blood agar plates. The crude filtrate also was found to have an abortive action on certain local human infections such as furuncles and carbuncles when injected into the center of the lesion.

GEORGE W. RICHARDSON, M.D.

Anderson, A. B.: Anaphylactic Purpura following Intramuscular Penicillin Therapy. *Med. J. Australia* 1947, 305.

The author gives an account of a case of anaphylaxis, apparently resulting from penicillin therapy, and manifested by transient swelling of joints and subcutaneous tissues, intestinal purpura, and toxic nephritis.

The patient was a 37 year old male who had no family history of purpura. He was admitted to the hospital for operation for an osteosarcoma of the lower end of the femur. On the nineteenth post-operative day there was purulent discharge from the wound. Penicillin therapy 15,000 units every 3 hours, was begun; a total of 500,000 units being

Intravenous injection (at a standard rapid rate) in mice of a solution stored for 13 days at 18 to 22 degrees C. failed to reveal any significant change in AD₅₀, LD₅₀, and LD₅₀/AD₅₀. Statistical analysis of the bio-assay data however showed that although no deterioration was demonstrated a 10 to 15 per cent loss of potency might have been obscured by the error of the method.

It is suggested that if a 5 per cent bulk solution of pentothal sodium is to be used on successive days, it should be stored in the refrigerator and discarded according to the usual practice when turbidity appears, but until further information is available the solution should not be kept longer than 3 days at 18 to 25 degrees C. or 7 days at 5 to 6 degrees C.

MARY FRANCES POZ, M D

Allen E. G., and Eversole U. H.: The Use of Curare in Anesthesia. *A. England J. M.*, 1947 236 593.

In a historical summary of curare, full credit for the modern development of the drug is given to Gill for its pharmacological and clinical trial full credit is given to McIntyre and Bennett. To Griffin and Johnson goes the credit for the introduction of curare to the field of anesthesiology in 1942. The mechanism of physiological action is discussed although the exact nature of this mechanism is not completely understood. The administration of curare produces a paresis or paralysis of the voluntary musculature throughout the body. It is supposed that the drug has no central action but further experimental work may disprove this assumption. No electrocardiographic changes in either normal or diseased hearts are noted during the administration of curare. The hypotension seen after curare is transient. The pulse is unaffected. The drop in blood pressure is only about 30 mm. of mercury and it usually lasts only a few minutes. It is questionable whether this is the result of a block in transmission between preganglionic and postganglionic fibers in the sympathetic system or of poor peripheral venous return as the result of the loss of muscle tone. A temporary loss of tone and peristaltic activity of the small bowel is produced with curare. It is rapidly eliminated from the body and most of it is broken down in the liver the remainder being excreted unchanged by the kidneys.

The method of administration may be that described by Griffin and Johnson or by Cullen. In small infants doses of 4 to 6 mgm. have been employed. The anesthetist must be prepared to treat respiratory depression or apnea, to maintain adequate airway and to understand endotracheal technique. Smaller doses are used for patients who are in shock, or are elderly or debilitated. Curare is best combined with cyclopropane. It neither increases nor decreases the irritability of the heart in this combination. When the weaker gases nitrous oxide and ethylene are used much larger doses of curare are needed. Caution must be taken when it supplements ether anesthesia as a cumulative action seems to take place. Favorable results occur with the

combination of curare and pentothal. The pure crystalline product obviates the disadvantages of precipitation occurring with this combination.

The contraindications include myasthenia gravis inadequate airway and suspected liver and renal damage. Although prostigmin is a direct antidote artificial respiration is the best treatment. Curare has proved to be a valuable adjunct to spinal anesthesia in abdominal operations for massive hemorrhage, bronchoscopies and esophagoscopies and for more extensive operations such as laminectomies, splanchicectomies and intrathoracic operations.

Thus curare has proved itself in the course of a few years to be of considerable value in the field of anesthesiology. It is not a panacea, but it is a useful adjunct and further investigation and research will set its true pattern in clinical applicability.

MARY KARP M D

Wiggin S. C., Schultz, P. E., and Saunders P.: Experience with Curare in Anesthesia. *A. England J. M.*, 1947 236 596.

The main purposes of this paper are to consider the indications for curare, its comparison with other agents, and to present experience with the use of curare (intocostarin) in 450 cases. The cases were divided into four groups. The first group were elective abdominal surgical cases in which curare was administered. The second group included cases in which a single dose spinal anesthetic for abdominal surgery was used, the third group consisted of poor risk patients and the fourth group comprised patients who required endotracheal anesthesia.

Experience with the cases of the first group led to the conclusion that the order of choice of anesthesia for abdominal procedures was as follows: (1) spinal anesthesia, (2) general light anesthesia with curare, (3) deep general anesthesia or other methods. The management of cases in which spinal anesthesia is wearing off and in which the intra abdominal surgery must be continued has been simplified by the introduction of curare. In such cases, light halothane anesthesia or pentothal plus curare has provided the needed relaxation in anesthesia for the completion of surgery.

The use of curare in poor risk patients has been facilitated by the use of light cyclopropane anesthesia with small doses of curare. Satisfactory anesthesia can thus be accomplished by their balanced use with small doses that, if used alone, would be insufficient. There have been no cumulative effects from these small doses. The use of curare to facilitate intra tracheal intubation adds another method to the various techniques of preparing patients for intubation. The advantage of this procedure is that it allows the anesthesiologist to use a light level of general anesthesia and to obtain complete relaxation in a relatively short time. The possible respiratory embarrassment following intubation is a disadvantage.

The authors state that the recovery period in all cases of all four groups was generally uneventful and

Toxic reactions observed in 2 patients were morbilliform rashes with eosinophilia, albuminuria and some pyrexia. One patient had vertigo.

Laboratory studies show that an additional effect is obtained from the use of subinhibitory concentrations of streptomycin and penicillin. Competitive excretions result in higher drug levels when both agents are parenterally administered simultaneously.

It is recommended that large doses of streptomycin be employed routinely in the beginning of therapy. From an analysis of results, it is apparent that streptomycin therapy in bacteremia can be expected to be successful if (1) the organisms are susceptible *in vitro* (2) dosage is adequate, the interval between doses provides bacteriostatic blood levels and the duration of treatment is long enough (3) surgical drainage of the primary focus is prompt and exact, and (4) due consideration is given to the management of the patient as a whole.

GEORGE W. RICHARDSON, M.D.

ANESTHESIA

Trifari, L. M., and Martin, S. J. Civilian and Military Aspects of Intravenous Anesthesia. *C. and Res. Anesth.*, 1947 26 45.

Intravenous anesthesia has followed the pattern of marked enthusiasm, followed by skepticism, and finally by a conservative and thorough evaluation so that now it is an accepted technique. Its historical technique is described, with emphasis on the role of pentothal sodium. The literary data to date are enumerated, and include conflicting views by various authors. The usefulness of intravenous anesthesia in neurosurgery, obstetrics, ophthalmology, otolaryngology and oral surgery, therapeutic, and thoracic surgery—are shown. Its use in military work was extensive in World War II and its popularity over shadowed the use of ether. Despite the initial cautions and adverse comments, the advantages of sodium pentothal have become more apparent when its limits and contraindications were fully appreciated. When anesthesiologists trained in its safe use became available, intravenous sodium pentothal was found to be just as effective and popular in the overseas military installations as in the Zone of the Interior.

Personal experience of the authors in over 4,000 administrations of sodium pentothal intravenous anesthesia corroborate the results of others. The principles of its administration, as first described by Lundy and set forth by Adams, are followed as far as possible. The intermittent method of administration of a 2.5 per cent solution was employed in all cases. Its major field of usefulness was found to be in orthopedic surgery as the sole anesthetic agent and, secondly as an induction agent for inhalation anesthesia. No deaths attributable to sodium pentothal occurred on the operating table, and no major complications were seen during the present series of

cases. The assets of simple equipment, nonemployability and ease of preparation were important factors in popularizing this agent among the overseas units.

Other barbiturates have been recently studied. These include such drugs as nembutal, ether, nembutal-barbital, cyclopal, and kemithal. Laboratory data concerning these drugs were described. The advantages of kemithal as pointed out by Halton were the notable absence of laryngospasm, the relaxation of masseter muscle, and the lack of depression of respiration. The technique of administration is described. Sodium succinate is considered a safe antidote against toxic doses of nembutal.

A discussion of curare gives it its proper place as an accepted agent in modern anesthesia. Its limitations, contraindications, and complications are now recognized and this helps to outweigh its disadvantages. With judicious use its popularity will continue to grow.

The authors discuss the use of intravenous procaine, the technique of injection, and its growing popularity. Despite the potential dangers of convulsions and severe asthma in the rare, true idiosyncrasy many advantages justify its continued clinical use. It has almost no effect on respiration, circulation, emetic center and diaphragm.

The clinical analysis of another intravenous agent, morphine is described.

The intravenous injection of ethyl alcohol is discussed from the standpoint of indications and contraindications. Its value includes analgesia, euphoria, caloric intake, and fluid intake.

Intravenous injections of other agents such as paraldehyde, avertin, ether and magnesium sulfate, to produce various depths of anesthesia, have failed to arouse significant enthusiasm. Thus intravenous anesthesia is now an established technique and is becoming increasingly popular in all English speaking countries. Particular emphasis is given to the recent reports on the pharmacology and clinical aspects of sodium pentothal, curare, and procaine administered intravenously.

The increase in volume and quality of the literature indicates that during the next few years anesthesiologists will make definite progress in intravenous technique.

Robinson, M. H. Deterioration of Solutions of Pentothal Sodium. *Anesthesiology* 1947 8 166.

A bulk solution of 5 per cent pentothal sodium prepared from the commercial ampules and kept for 65 days at room temperature of 18 to 22 degrees C. was found to deteriorate steadily with time as evidenced by the fall in melting point of extractable pentothal acid. When kept in the refrigerator at 5 to 6 degrees C. the rate of deterioration was greatly reduced. At the lower temperature sealing the flask as compared to leaving the solution open to the air prevented the formation of crystals on the surface of the fluid but had no demonstrable effect on the melting point over a period of 25 days.

Intravenous injection (at a standard rapid rate) in mice of a solution stored for 13 days at 18 to 22 degrees C. failed to reveal any significant change in AD₅₀, LD₅₀ and LD₅₀/AD₅₀. Statistical analysis of the bio-assay data, however, showed that although no deterioration was demonstrated a 10 to 15 per cent loss of potency might have been obscured by the error of the method.

It is suggested that if a 5 per cent bulk solution of pentothal sodium is to be used on successive days, it should be stored in the refrigerator and discarded according to the usual practice when turbidity appears, but until further information is available the solution should not be kept longer than 3 days at 18 to 22 degrees C. or 7 days at 5 to 6 degrees C.

Wiggin, S. C., Schultz, P. E., and Saunders, P.: Experiences with Curare in Anesthesia. *N. England J. M.* 1947 336 536

The main purposes of this paper are to consider the indications for curare, its comparison with other agents and to present experience with the use of curare (intocastin) in 450 cases. The cases were divided into four groups. The first group were elective abdominal surgical cases in which curare was administered, the second group included cases in which a single dose spinal anesthetic for abdominal surgery was used, the third group consisted of poor risk patients, and the fourth group comprised patients who required endotracheal anesthesia.

Experience with the cases of the first group led to the conclusion that the order of choice of anesthesia for abdominal procedures was as follows: (1) spinal anesthesia, (2) general light anesthesia with curare, (3) deep general anesthesia or other methods. The management of cases in which spinal anesthesia is wearing off and in which the intra abdominal surgery must be continued has been simplified by the introduction of curare. In such cases light inhalation anesthesia or pentothal plus curare has provided the needed relaxation in anesthesia for the completion of surgery.

The use of curare in poor risk patients has been facilitated by the use of light cyclopropane anesthesia with small doses of curare. Satisfactory anesthesia can thus be accomplished by their balanced use with small doses that if used alone, would be insufficient. There have been no cumulative effects from these small doses. The use of curare to facilitate intra tracheal intubation adds another method to the various techniques of preparing patients for intubation. The advantage of this procedure is that it allows the anesthesiologist to use a light level of general anesthesia and to obtain complete relaxation in a relatively short time. The possible respiratory embarrassment following intubation is a disadvantage.

The authors state that the recovery period in all cases of all four groups was generally uneventful and

brief. Three patients presented respiratory depressions, and these emphasized the importance of the physiological control of respiration during the operation, and the necessity of the same careful supervision of patients who are under the effect of curare in the postoperative period.

MARY KARP M.D.

Ostlere, G.: Curare in 'Poor Risk' Patients. *Brit. M. J.* 1947 448.

The present article is based on 136 surgical cases in which curarization was performed at Hill End Hospital (St. Bartholomew's). Limitation of supplies demanded a careful selection of cases curare being used almost exclusively for abdominal and chest operations, particularly with 'poor-risk' patients.

In abdominal cases, endotracheal intubation was performed after pentothal induction followed by the administration of nitrous oxide, oxygen, and trilene. Fifteen milligrams of curare were used if needed. Anesthesia was maintained by means of nitrous oxide-oxygen with minimal trilene from a semiclosed Boyle apparatus. It is important that only a trace of trilene be employed. Curare was given when the peritoneum was first reached further doses being added as relaxation demanded.

For thoracic cases, pentothal induction was followed by cyclopropane oxygen. Blind intubation and a throat pack were usually employed just before the patient was turned on the table 15 mgm. of tubarine were given. During maintenance if the respiration increased in depth 5 mgm. of tubarine were given while any movement or an increase in respiratory rate was considered an indication for more cyclopropane.

Twenty patients with eye complaints after the use of curare have been seen. Blurring of vision was the commonest fault complained of often accompanied by other defects such as ptosis and failure of accommodation.

The author's impression was that although curare proved an inestimable boon in the theater it had no effect on the frequency of postanesthetic vomiting, and possibly slightly reduced the incidence of anticipated chest complications. The greatest advantage of curare is that it enables very ill patients, particularly those needing thoracic surgery to undergo operation without a dangerously prolonged deep anesthesia and to recover rapidly from the immediate effects of the operation.

MARY FRANCES POT, M.D.

Barnes, J.: Pethidine in Labor. *Brit. M. J.* 1947 1 437.

This article embodies the results of the use of pethidine as an analgesic agent in over 300 cases observed in the Obstetric Unit at University College Hospital London, between the years 1942 and 1946. The dose used was 100 mgm., given by subcutaneous or intramuscular injection, and repeated as required. In many cases, pethidine was combined with other sedatives and analgesics, the patients receiving ni-

trous oxide-and-air analgesia or trilene in the later stages of labor. A single injection of 100 mgm. was adequate for the majority of labors, and a high proportion of the remainder required only two doses.

There was no maternal mortality. Slight toxic effects were noted in 11 mothers. These effects were transient. Signs of asphyxia were noted in 35 infants recovery occurred in all. Pethidine may have contributed to slight respiratory depression in a few cases. Good analgesia was experienced by 55 per cent of the mothers. Failures may be accounted for in some cases by the fact that pethidine was given too late in labor. Amnesia was obtained in only 10 per cent. No effect on uterine contractions was noted in 67 per cent of the mothers. The claim that pethidine shortens the duration of labor cannot be substantiated. No tendency to postpartum hemorrhage was noted.

Although pethidine does not fulfill all the criteria laid down by Sturrock for the ideal obstetric analgesic, it is suggested that it approaches the ideal more nearly than any other agent in current use.

MARY FRANCES POT, M.D.

Jarman, Ronald; Evans, Frankie; Lloyd Davies, O. V.; Vessell, V. Eades; Dals, H. W. Loftus; and Goldman, Victor: Discussion of Anesthesia for Abdominoperineal Operations for Cancer of the Rectum. *Proc. R. Soc. M. Lond.* 1947 40 363.

JARMAN. The anesthesia technique for operations for cancer of the rectum has been more or less standardized. The method of choice is pentothal, spinal block, and nitrous oxide-oxygen. An adrenal drip during operation permits control of hypotension. Blood transfusions are given immediately after operation. Fourteen days of observation and preparation prior to operation are important. The patient is taught to use his muscles while lying in bed, especially how to breathe and use his abdominal muscles.

EVANS. The preference is for a spinal analgesia in combination with a dilute pentothal drip for excision of the rectum. This method diminishes nerve shock and tends to lower the blood pressure these results are advantages. A heavy solution of nupercaine is used for the spinal block the analgesia level being limited to the costal margin.

A special cannula has been designed for the intra-venous infusion. The adrenalin drip is started if the blood pressure falls below 80 and is continued post-operatively. In all cases, blood is given during the operation.

LLOYD-DAVIES. Turning the patient during operation can be avoided by using the lithotomy Trendelenburg position. If adrenalin has been used during the operation it must be continued in the ward until the normal vasomotor control recovers.

VESELL. Early blood transfusion during the course of operation is strongly recommended.

DALS. Cyclopropane in conjunction with spinal analgesia for abdominoperineal excision is prefer-

able to ultrous oxide as it permits an increase of oxygen. Recently spinal analgesia have been abandoned in favor of cyclopropane and curare to avoid the fall in the blood pressure.

GOLDMAN Since light cyclopropane anesthesia is generally employed, the use of adrenalin is not recommended. Instead methedrine is added to the saline infusion.

ROWBOTHAM He has given up the use of adrenalin since plasma or serum has become available and is of the opinion that the use of plasma or serum is superior to that of many analeptic drugs.

MARY FRANCES POE, M.D.

Whitehead, R. W. and Draper W. B.: A Respiratory Reflex Originating from the Thoracic Wall of the Dog. *Anesthesiology* 1947 8: 159.

The authors' experiments have revealed the existence of a respiratory reflex which is more effective in anesthetic depression than is either tongue traction or anal stretching. It is initiated by the applica-

tion of light pressure to a localized area of the chest wall.

The thoracic wall reflex has the following characteristics: the adequate stimulus is light pressure; the respiratory act induced is carried out in a smooth and normal manner and is largely diaphragmatic; fatigue of the reflex may occur but its sensitivity is rapidly restored; the reflex is susceptible to inhibition and may disappear in severe hypoxia or shock.

The reflex was obtained following very light pressure applied to the distal end of the scalenus medius muscle and its tendon or to the proximal end of the rectus abdominis muscle and its tendon. It may be significant that the reflex arises with apparently equal power from two muscles and their tendons which have opposite respiratory functions, and which in the dog happen to be in close anatomical relation.

The existence of this reflex in the human is undemonstrated but if present should prove a valuable aid to resuscitation.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Leriche, R.: Surgical Treatment of Sjögren's Syndrome, Dry Eye and Mouth. *End Results 28 Months after Bilateral Section of the Vertebral Nerve. Nature of the Disease (Traitement chirurgical du syndrome de Sjögren, Oeil sec et bouche sèche. Résultats à bout de vingt-huit mois d'une double section du nerf cervical. Nature de la maladie).* *Presse méd.* 947 55 77

On June 15 1946 Clement called the attention of the medical profession to the rare syndrome of Sjögren which is characterized by dryness of the eyes and mouth and has no known treatment. The author recalls having seen a patient in 1939 who showed these findings, and be presented a complete and detailed history of the case.

A 50 year old woman consulted the author because of dryness of the mouth and eyes of about 5 years duration. Shortly before the onset of her illness she was involved in a car accident in which she sustained severe trauma to the head with loss of consciousness. Following this she suffered from occipitotend pain, and soon noticed that she had almost no saliva even while eating. At about the same time her teeth which had always been in excellent condition, began to disintegrate and all of them had to be extracted. There was, however, no impairment of her sense of taste smell or hearing. Her appetite remained good. Three years prior to admission her eyes became dry. The lids were normal but a few of her eyelashes were falling off. Shortly thereafter her eyes became so dry that she was unable to cry and it became necessary for her to carry a small bottle of water to moisten them as well as her mouth. One year prior to admission she developed considerable painful swelling of both parotid glands, and pus could be seen exuding from Stensen's ducts.

At the time of physical examination by the author there was comp. dryness of the mouth, lips tongue soft palate, pharynx, and eyes. There was no sign of conjunctivitis. Large drops of pus could be seen at the ostia of Stensen's ducts. A few small telangiectasias similar to scleroderma but without skin atrophy were present on the face which was somewhat shrunken due to depression of the parotid and submaxillary regions. On the basis of these findings the author as well as a medical consultant made a tentative diagnosis of atypical scleroderma.

The patient was observed for several days while attempts to revive the lacrimal and salivary gland through the production of hyperemia by sympathetic block were undertaken. Since these proved effective an operation on the sympathetic system was done. The roots of the right vertebral nerve were severed and a fragment of the cervical sympathetic chain above the stellate ganglion but including the middle cervical ganglion was resected. The same night of

the operation both subjective and objective improvement was noted. Five days later the left side was done with the same result. Immediately following operation the telangiectasias almost disappeared. Four days later the patient salivated some thick saliva. In 8 days the patient was discharged, having lost the annoying sensation of dryness of her eyes and mouth. Soon she was able to cry. These results remained permanent for 28 months when she died from acute hemorrhagic purpura.

In the author's opinion two obvious conclusions can be drawn from this case.

1. The patient presented a true case of Sjögren's syndrome. Nothing was lacking. There was dryness of the eyes mouth, and pharynx with parotid and submaxillary atrophy.

2. Bilateral section of the cervical sympathetic nerve proved effective both subjectively and objectively. On the basis of this result early surgery is indicated for relief of symptoms and to prevent atrophy of the parotid and submaxillary glands. This proposal can be justified by the following:

In all cases of Sjögren's syndrome which have been biopsied or autopsied atrophy of the salivary and lacrimal glands has been present. The author believes that this atrophy is due to a decrease in blood supply either from arterial obliteration or vasoconstriction. To prevent the atrophy and trophic disturbances in this syndrome, one must improve the deficient local circulation. This is accomplished by sectioning the cervical sympathetic chain, which abolishes vasoconstriction and also makes the glands more prone to respond to stimuli from the secretory fibers of the innervating nerves. In mild cases, periarterial sympathectomy and repeated novocain blocks may suffice but in severe cases cervical sympathectomy becomes necessary. In doing the sympathectomy the stellate ganglion is not removed in order to maintain the accelerator fibers of the heart and vasoconstrictor fibers of the upper limb. The resection of the second and third dorsal ganglion is also unnecessary.

In his case Leriche severed the branches of origin of both vertebral nerves. This was perhaps not the ideal operation although the result was good. Perhaps better results could have been obtained if resection of the middle portion of the cervical chain and removal of the middle cervical ganglion up to the lower pole of the superior ganglion had been carried out.

In the last part of his article, Leriche tried to determine the place of Sjögren's syndrome in the nosography. Is this disease simply a local process of vascular or vasomotor origin? Is it an elective atrophy of the glands? The author came to the conclusion that there is no relation between this syndrome and atypical scleroderma. It is, according to him an elective atrophy of the lacrimal gland and

all of the salivary glands. Having observed the peculiar dental disturbances of his patient and noting that her death was due to hemorrhagic purpura, the author believes that this might be a systemic disease at least in its origin. A disturbance of the neuro-vegetative system has been mentioned as the pathogenesis. This is somewhat vague and without microscopic examination of the prevertebral ganglionic one cannot substantiate such a hypothesis.

The author advised that histologic examination of the sympathetic ganglia and arteriography through the external carotid artery be done to add to the knowledge of this peculiar disease.

GERARD GAGNON, M.D.

Darmady, E. M.: Renal Anoxia and the Traumatic Uremia Syndrome. *Brit J Surg* 1947 34 262

It was the experience of the staff at an R.A.F. Casualty Clearing Station in England that successful surgery was often marred by the onset of uremia which sometimes proved fatal. Among 10,000 casualties admitted there were 44 deaths, and in 12 of these, death was directly due to renal failure. Biochemical investigations were continued and the present report deals with a further 6 cases of fatal traumatic uremia and 3 more cases of uremia with recovery. It is clear that the biochemical course of all the cases and the histological changes found post mortem in the fatal cases are sufficiently similar to warrant the assumption that some common factor was operative in producing the uremia.

The clinical features are characteristic. In the series under consideration all were severely wounded men who had suffered considerable loss of blood accompanied by shock requiring energetic resuscitative measures. Thus in many cases prolonged periods of hypotension were recorded. The onset of symptoms took place between the second and sixth day after injury. Usually the first sign was anorexia with a tendency to hiccup and this was followed in the course of a few days by copious vomiting. The tongue was dry and brown, and the patient was drowsy with attacks of hallucinations. Cyanosis was frequently present. Occasionally a petechial rash was seen over the upper parts of the body. This was thought to be a manifestation of fat embolism (a common feature in severely wounded casualties). During the prodromal period oliguria was present, although this was not always obvious unless a fluid intake and urinary output chart was kept. All the patients whose cases are recorded had an enormous rise in blood urea, oliguria, and a disturbance of electrolyte balance. The highest blood urea recorded from this series was only 66 mgm. per cent. The urinary urea remains constant at values between 1.8 and 5.5 mgm. per cent in spite of the fact that the blood urea value swings between 496, 461 and 473 mgm. per cent. The specific gravity of the urine remained between 1014 and 1018. The pH of the urine did not vary with the alteration in alkali reserve (44 to 66 volumes per cent) but remained at 6.4-6.6 and 6.8.

Disturbance of electrolyte balance. This presents several problems since not only was there an acidosis, but also hypochloremia. It was easy to alter the alkali reserve by treatment with intravenous sodium lactate but the restoration of the alkali reserve was difficult to maintain. Even if the electrolyte balance of the blood is corrected early the disease is still progressive and there is a continued rise in blood urea. The author made a study of the macroscopic and microscopic findings at autopsy along with the etiological factors and the similarity to other conditions and concluded that the ultimate cause of the death is renal anoxia.

The mechanism of the production of renal anoxia by alteration of the blood supply to the kidney by vasospasm is problematical. There is an immediate alteration in the CO_2 -combining power from the intravenous use of 5 c.c. of molar sodium lactate solution but the response to sodium chloride is slow. The body conserves its stock of sodium chloride after depletion for even after the blood chloride has returned to normal there is no secretion of chloride in the urine for 3 to 4 days. The fact that an acid urine may be secreted in the presence of alkalosis has been noted again and again. A general survey of the present series and the cases in the literature would seem to indicate that it is more important to correct the salt deficiency than the alkali reserve, but since a low alkali reserve and low blood chlorides have been found in other wounded men it is believed that the electrolyte balance does not in fact, play a major part in the production of traumatic uremia. It would appear that the tubular change is the essential and characteristic lesion in these patients dying of uremia and that the presence of pigment casts is incidental. The most acceptable theory seems to be that of renal anoxia which may well be brought about by vasospasm. This in its turn may be produced by various conditions such as shock, sensitizing antigens, dehydration and hypochloremia. Trueta (1945) has drawn attention to the fact that in shock overstimulation of the peripheral nerves may cause persistent spasm of renal and other arteries and this would lead to interference with the blood supply and result in renal anoxia.

The dangers of overalkalinization and possible help through splanchnic block, are indicated in the case of a Polish private who was wounded on April 25, 1945 by a gunshot wound of his left buttock and thigh. On the following day his leg was found to be ischemic, and the femoral artery injured. An immediate amputation was performed through the thigh. His postoperative condition was described as only fair. Five days after wounding he started to hiccup, and on the sixth day he was evacuated by air and admitted to Wroughton. He was now vomiting and his blood urea was found to be 500 mgm. per cent. His fluid intake was limited and on the eighth day after wounding his blood urea had risen to 820 mgm. per cent. Splanchnic block was then performed. His blood pressure fell, and on the ninth day after wounding his blood urea had fallen to 220 mgm. per

cent From this day on his condition rapidly improved. He was transferred 27 days after wounding his blood urea being 40 mgm. per cent on discharge.

C. FRED GORDON, M.D.

King, E. S. J.: The Nature of the Pilonidal Sinus. *Austral & Zealand J Surg* 1947 6 152.

The author believes that pilonidal sinuses are not the result of an error in fetal development. It is his belief that there is an irritation of the skin of the sacrococcygeal region of an adult which leads to a crypt formation by widening of a hair follicle or formation of a simple depression. Gradual deepening of the crypt and downgrowth of the epithelium into the subcutaneous tissue occur next. The crypt becomes the repository of debris, including hairs (which enter the sinus from without) and these cause persistent inflammation and the discharge of purulent material. This chronic inflammation results in further epithelial downgrowth. Acute exacerbations cause abscesses and fistulas or a furuncle or primary abscess bursting in or near the midline may in a similar manner become a reservoir for foreign material. It thus may become chronic and ultimately epithelization may take place.

The main features which support this hypothesis and which are not explicable on a "congenital" basis are (a) the maximum incidence in the second and third decades (b) the formation and regression of sinuses (c) multiple lesions (d) lesions not in the midline (e) the stages of development observed in adjacent sinuses, both macroscopically and macroscopically (f) the presence of hair as a foreign body and not a local formation.

An important result of this review is that in the early stages, the condition is preventable and is responsive to conservative treatment. The important point is that due attention be paid to irritative conditions in this area. In addition, an essential part of the treatment of a developed lesion whether it be an abscess or a postoperative healing area, is that particular care must be exercised to prevent the entry (since this occurs so readily here) of any foreign material into the area. JAMES WEAVER, M.D.

Morone, C. Melanotic Blastoma Occurring on an Ulceration Resulting from Trauma (Blastoma melanotico in sito su ulcerazione prodotta in seguito trauma) *Riforma med.*, 947 6 6.

The author reports a case of melanosisarcoma which appeared on the foot of a 37 year old man in whom a forced march in improper shoes had resulted in an exudative ulceration. The exudate was thin and blackish, but in spite of various methods of treatment, the ulcerated area extended and proliferation was marked. Regional glands appeared and nodules later developed on the thorax slightly above the left nipple. Axillary glands were also noted.

Histological study of an inguinal gland removed for biopsy revealed a neoplasm involving pigmented cells derived either from the germinal layer of the epidermis or from the pigment cells of the corium. The possible derivation of this tumor from epithelial or mesodermal elements is discussed as well as the possibility of a pre-existing lesion antedating the traumatic experience. The opinion is expressed that the lesion was of connective tissue origin hence, truly a melanosisarcoma, and that its appearance and development were probably stimulated by sustained trauma and long standing inflammation.

HOSPITALS MEDICAL EDUCATION AND HISTORY

Frankel, Walter K.: Paracelsus, The Founder of Occupational Medicine. *Occup M* 1947 3 283.

Occupational medicine was almost unknown in ancient times and in the middle ages. Occupational diseases are closely connected with industrialization and industrialization did not exist during those times. All manufacturing processes were based on individual manual labor in small enterprises. The environmental conditions of the work shop were not so different from the housing conditions in general as to injure the health of the workman. Where production necessitated collective labor with the accumulation of workers under less satisfactory outside conditions work was done either by slaves, as in Egypt, Babylonia, Assyria, Greece, and the Roman Empire or by unfree and unskilled workers. The social position and valuation of these groups of laborers were so low that their health was not of any interest either to their employers or to physicians. Labor and laborers were so cheap that the health of workmen and the continuity of their productivity did not influence either production or the market prices of the product, even if there was much absenteeism caused by diseases or epidemics.

In antiquity there was collective labor only in few fields of activity such as the erection of great structures and mining.

Miners' diseases did not attract the attention of the great masters of medicine and were not described in their works until about 400 years ago. At that time Paracelsus wrote his treatise "Von der Bergsucht" (literally, "About Mountain Consumption"), in which he made detailed and exact descriptions of injuries to health found so frequently in men working in the mines, injuries suffered either in the pits or from the products hauled out of the pits or from processing these products. With this book, Paracelsus established a new medical entity occupational disease and inaugurated a new branch of medical knowledge and research occupational medicine.

APPLIED ANATOMY OF THE FEMORAL VEIN AND ITS TRIBUTARIES

EDWARD A. EDWARDS M.D., F.A.C.S., and JOHN D. ROBUCK, Jr. Boston Massachusetts

FOR a variety of reasons, the femoral vein has become the object of frequent surgical attack yet the arrangement of the trunks entering this vessel and the pathways for its collateral circulation are not well known. Chief among the present indications for operation on the vein is the presence of venous thrombosis in the leg or thigh. The anatomy of the femoral vein will here be considered in special reference to its surgical interruption for this disease to prevent the transport of thrombotic emboli.

The usual textbook description of the femoral vein lists its tributaries as the saphenous and the deep femoral veins with only a few additional minor muscular tributaries. Yet, at operation it is apparent that several large veins enter the femoral under the deep fascia. The surgeon's problems are first to determine, within the limited exposure of his incision which of these is the deep femoral vein and which other vessels whose more transverse course in the upper thigh are less likely to transmit either the thrombosis itself or an embolus from the lower thigh, second to identify possible collateral channels of the femoral vein of a size sufficient to carry emboli around his interruption of the main trunk third to know where best to place his ligature with reference to the main anastomotic pathways from the femoral vein to the pelvic veins.

From the Department of Anatomy Harvard Medical School.

OBSERVATIONS

To shed light on these questions we have examined the arrangement of the femoral venous system in 61 extremities in the dissecting room. Previous anatomic investigations while excellent in many ways still fail to answer our problem satisfactorily. These previous investigations and the results of the present study will be considered under the separate headings of anomalies of the femoral vein proper tributaries of the femoral vein its collaterals, and finally anastomotic pathways from the thigh.

A glance at the accompanying diagrams impresses one with the great variations that exist both in regard to the pattern of the venous channels and the levels of their termination in the femoral vein. Moreover the vessels not only vary greatly from one individual to another, but also often fail to show a bilateral symmetry in the same individual. In the diagrams the terminations of all the large venous trunks have been recorded and care has been taken to locate accurately to scale, the vertical relation of these levels to the inguinal ligament. It is probable that in most live individuals the ligament would be stretched downward 1 centimeter or more below its position in the thin cadavers studied.

1 Anomalies of the femoral vein proper The only gross anomaly of the femoral vein proper encountered in this study was the termination of this vessel in the hypogastric (Fig. 9)

Fig. 2. Varieties of communications between the deep femoral and femoral veins. In a and c, the lower deep femoral has gross communications with the femoral. In c, left, the deep femoral is doubled. In b and d, are varieties of communications of the upper deep femoral vein.

ductor canal with rather transverse courses to the contiguous muscles.

Returning to our observations on the veins it was apparent that the *venae comitantes* of the musculoarticular and saphenous arteries did not often join to form a *supreme genicular vein*. When this did occur the resulting vessel was slender and paralleled the femoral vein for long distances, appearing as a collateral

vein, until it emptied into the femoral, or terminal deep femoral vein (Figs 1-3).

Our observations go even farther than those of Charles and his associates in pointing to the infrequency with which the *deep femoral* receives the circumflex femoral veins. In a larger series than the present namely 165 extremities these workers found that the circumflex veins emptied wholly into the femoral

Fig. 3. Varieties of collateral femoral veins. None extend much higher than the deep femoral ending. I and c, apparent collaterals are actually the supreme genicular veins. In d, there is "double" femoral vein.

vein proper in 76 per cent. In our study the deep femoral received the medial femoral circumflex but once the lateral, five times. More over the venae comitantes of the first or second perforating arteries may likewise enter the femoral (Fig. 2 b d). We may therefore define the deep femoral vein as the vessel resulting from the fusion of the lower perforating veins usually receiving the upper perforating veins, and occasionally the circumflex femoral veins.

The deep femoral vein (figs. 1-2) is almost always the most inferior of the large venous channels entering the femoral though a low lateral femoral circumflex vein or an exceptional collateral may enter at this level. The deep femoral vessel terminated in the femoral vein at an average of 8 centimeters below the inguinal ligament. The shortest distance was 5 centimeters the longest 11.5 centimeters. There was only approximate correspondence with the height of the individual. Moreover while

bilateral equality of level was the rule exceptions were found varying up to 3 centimeters.

In 6 instances the inferior end of the deep femoral vein showed a large communication with the femoral just above the adductor opening. It is obvious that such a connection must be taken into account as a possible pathway for extension of a thrombus or an embolus from a process in the popliteal or lower femoral vein. In 3 instances (Fig 2 b d) the deep femoral terminated by 2 mouths entering the femoral vein. Such a communication would again be of significance in an attempted interruption. In 3 cases the deep femoral showed doubling.

The *lateral femoral circumflex vein* usually emptied into the femoral above the deep femoral vein. Often the tributaries corresponding to the 3 main divisions of the artery remained as separate trunks so that 2 or 3 lateral femoral circumflex veins were not uncommon and the lowest of these sometimes ended in the deep femoral.

The *medial femoral circumflex vein* was ordinarily the highest of the large veins to enter the femoral ending at or above the level of the saphenous termination. It was usually single. When it terminated as two veins the upper occasionally received the small deep external pudendal vein. In most instances however this vein ended directly in the femoral.

The superficial subinguinal veins, including the *superficial epigastric circumflex iliac* and *external pudendal* veins ended as small vessels in the terminal *saphenous* or occasionally directly in the femoral vein immediately above the saphenous. Little additional need be said of the saphenous vein. Its anatomy has been covered in a previous report (4). Its termination in the femoral is of course easily seen lying as previously reported at an average of 1.7 centimeters below the pubic tubercle which corresponds quite well to a point four centimeters below the inguinal ligament as measured in the present study.

Additional veins terminating in the femoral were irregularly placed and generally small tributaries from the muscles as well as collateral veins and circles to be described in the following.

Fig 4. The collateral venous plexus in the posterior thigh. The deep veins were injected after the femoral was tied at the inguinal ligament. (From Hovelacque.)

3 *Collaterals of the femoral vein* Clinically the term collateral is used to denote any anastomotic channel. Anatomically the word is more limited and it may be well to define it now in order to differentiate collaterals from the venous circles to be mentioned in the next section. The characteristics of a true collateral have been summarized by Hovelacque. It is a vessel that runs parallel to a more important vein and communicates with the major vein at its two extremities. In this

There was only approximate correspondence with the height of the individual. Moreover while

Fig. 9. Benign lymphoid polyp of the rectum. The head of the polyp is composed of hyperplastic lymphoid tissue with scattered secondary nodules. These lesions have been cured by local excision and have never been followed by malignant changes (the 53 seen in the ALI) (X 35 ALI Acc. 1479)

where in this survey. Glandular polyps which were discovered in the intestinal tract during autopsy when death had resulted from other causes, were not included in this series. It follows, therefore, that the polypoid lesions of the intestinal tract in the present series were nearly all instances of a primary clinical disease. Only a general statistical survey of adenomatous polyps has been attempted. Analysis of this material as to its relation to the genesis of cancer of the intestinal tract would need to be the object of a special study.

The 3 instances of diffuse polyposis of the large intestine all occurred in white males and

Fig. 10. Esophageal cyst found in all of esophagus lined with columnar epithelium. The muscularis propria surrounds a part of the esophageal wall (X 45 ALI Acc. 14720)

all terminated fatally with death the result of surgical complications. Adenomatous polyps totaled 135; 105 of these were located in the rectum; the remainder were distributed throughout the intestinal tract as indicated in Figure 8. In 10 instances the diagnosis bore the qualifying phrase "with cellular atypism" or with early carcinomatous change. There were no fatalities recorded in the entire group. There were 12 females in the series, 11 negro males, and 1 mongolian male. So far as is known all

bilateral equality of level was the rule exceptions were found varying up to 3 centimeters.

In 6 instances the inferior end of the deep femoral vein showed a large communication with the femoral just above the adductor opening. It is obvious that such a connection must be taken into account as a possible path way for extension of a thrombus or an embolus from a process in the popliteal or lower femoral vein. In 3 instances (Fig 2 b d) the deep femoral terminated by 2 mouths entering the femoral vein. Such a communication would again be of significance in an attempted interruption. In 3 cases the deep femoral showed doubling.

The *lateral femoral circumflex vein* usually emptied into the femoral above the deep femoral vein. Often the tributaries corresponding to the 3 main divisions of the artery remained as separate trunks so that 2 or 3 lateral femoral circumflex veins were not uncommon and the lowest of these sometimes ended in the deep femoral.

The *medial femoral circumflex vein* was ordinarily the highest of the large veins to enter the femoral ending at or above the level of the saphenous termination. It was usually single. When it terminated as two veins the upper occasionally received the small deep external pudendal vein. In most instances however this vein ended directly to the femoral.

The superficial subinguinal veins including the *superficial epigastric circumflex iliac* and *external pudendal* veins, ended as small vessels in the terminal *saphenous* or occasionally directly in the femoral vein immediately above the saphenous. Little additional need be said of the saphenous vein. Its anatomy has been covered in a previous report (4). Its termination in the femoral is of course easily seen lying as previously reported at an average of 17 centimeters below the pubic tubercle which corresponds quite well to a point four centimeters below the inguinal ligament as measured in the present study.

Additional veins terminating in the femoral were irregularly placed and generally small tributaries from the muscles as well as collateral veins and circles to be described in the following.

Fig 4. The collateral venous plexus in the posterior thigh. The deep veins were injected after the femoral was tied at the inguinal ligament. (From Hovelacque.)

3 *Collaterals of the femoral vein* Clinically, the term collateral is used to denote any anastomotic channel. Anatomically the word is more limited and it may be well to define it now in order to differentiate collaterals from the 'venous circles' to be mentioned in the next section. The characteristics of a true collateral have been summarized by Hovelacque. It is a vessel that runs parallel to a more important vein and communicates with the major vein at its two extremities. In this

Fig. 5. Venous circles. On the left the medial femoral circumflex vein anastomoses with the obturator and on the

right, its posterior portion enters the inferior gluteal. Arrows indicate valve orientation. (From Braune.)

way it extends from one segment of the parent vein i.e. a portion between two valves, to another segment. Valves are usually present in the collateral and are always directed centripetally. The rôle of collaterals is denoted in their being termed *canaux de sûreté* (Verneuil 5). Their functions are to receive overflow from the principal vein—preventing stasis, equilibrating pressures and relieving valves in the main trunk from excessive strain. Picqué and Pigache, finding more and larger collaterals of the femoral vein in the newborn thought them to be vessels in a state of “regressive atrophy.” While this may be true it hardly explains their occurrence although it may prove that the body economy may not demand their persistence in their original size.

Langer had insisted that quite constantly two or three collateral femoral veins are present. From the present study one may agree that at least one such vessel is almost always present though so small as to be easily overlooked. The form of collaterals coincides quite

well with the descriptions offered by Langer and by Picqué and Pigache. The vessels are generally narrow longitudinally disposed channels, originating in the popliteal or the lower femoral veins. They are remarkable for the limited number of their communications with the femoral and for their termination in the lower levels of that vein. It is rare to find them continued above the ending of the deep femoral vein. Moreover they receive but a few tributaries, which are small veins from the muscles. The supreme genicular vein often ascended for long distances and appeared as a collateral vessel. This is also mentioned by Hovelacque who adds that an articular vein from the popliteal region may also constitute a collateral. “Insular” formation by division of the femoral, and fusion at a higher level has been observed.

Great enlargement of a collateral to give doubling of the femoral vein was encountered only twice. One may agree with Picqué and Pigache that even in these instances each

of the pair of veins receives the tributaries characterizing the usual femoral vein and a collateral, respectively. Moreover a doubling of the femoral vein was never seen in its upper most portion.

Mention must here be made of the anastomotic chain in the posterior thigh effected by the junction of the perforating and both circumflex femoral veins with the popliteal below and the inferior gluteal above (Fig. 4). The pathway thus formed constitutes an additional collateral system for the femoral vein. The inconstancy of its popliteal connection tends to reduce its usefulness. Moreover its valves are arranged as in a venous circle, that is for flow to each segmental parent trunk rather than for an uninterrupted upward flow. Apparently however the veins of this pathway dilate easily rendering the valves incompetent, for it is shown to be the most important anastomotic pathway in interruptions of femoral vein at any level (6).

It may be well to note that two other veins beside the femoral assist in drainage from the upper thigh namely the inferior gluteal and the obturator. Their direct drainage is so limited however that they perform this function mainly through their anastomoses with tributaries of the femoral vein. We may now consider in more detail the nature of these and other anastomoses at this level.

4. *Anastomotic pathways from the thigh* It will be recalled that true collateral vessels were found anastomosing with the femoral vein but reaching no higher than the deep femoral termination. Above this point only occasional collaterals exist, in the form of arcades along the constituent trunks of the medial or lateral circumflex veins. Only exceptionally are the anastomoses found valved for centripetal flow from the femoral to the iliac veins. Instead these communications are valved so as to form channels denoted by Braune as venous circles. In these (Figs. 5 and 6) the valves are so oriented that blood may flow into each of the veins, or vein segments, which the circle connects but not from one level to the other. In order to function as collaterals, it is therefore necessary that such vessels undergo a preliminary dilatation to render the valves incompetent.

Fig. 6 The lateral femoriliac circle. A deeper component is shown in the lower right. Arrows indicate valve orientation. (From Braune.)

The largest of the venous circles encountered was the bifurcated pathway constituted by the inoculation of the medial femoral circumflex vein with the obturator and inferior gluteal veins (Figs. 7, 8, 9). The prime importance of these pathways has been indicated by the injection experiments of several workers (2, 5, 6, 10). These are not only the largest of the anastomoses from the femoral vein upward but moreover as Braune pointed out valves may be lacking in the medial femoral circumflex vein allowing an immediate centripetal flow (Fig. 8 a, d).

Accessory routes in this vicinity probably arranged as venous circles, are the communications between the deep external pudendal and the internal pudendal and obturator veins, as well as with the deep dorsal vein of the penis. The latter in turn empties into the vesicoprostatic plexus within the pelvis. Here experiments (1, 6) indicate that the sacral veins, and the entire vertebral system of veins, aid the iliac in carrying the blood upward.

Fig. 7. Varieties of valvular arrangement in the gross anastomotic channels of the femoral vein. The veins collateral to the lower femoral vein are valved centripetally. The veins extending from the upper femoral to the iliac veins are valved toward each parent trunk. In both 'a' and 'b', the anastomosis from the medial femoral circumflex to the inferior gluteal is incomplete. In 'b', the lateral femoroiliac circle is incomplete.

In lateral relation to the femoral vein lies a venous circle described by Braune as the circumflex iliac circle, and denoted here as the lateral femoroiliac circle (Figs. 7, 8, 9). This vessel extends usually from the lateral femoral circumflex vein or the femoral above this level, to connect with the deep circumflex iliac vein. Connections with the superficial circumflex iliac vein were not uncommon and occasionally as Braune shows the circle may be made up of several vessels, some superficial, others deep to the femoral artery or nerve

(Fig. 6). The valves of this circle are rather perfectly oriented toward each of its two ends. This fact as well as its usual small caliber limits its immediate utility as an anastomotic path. Yet it would seem that this vessel deserves a place in our textbooks and in our thinking. It was found in the present study in 17 limbs, and it is the writer's impression that some small vessel or vessels representing it may be even more often observed. Moreover it is not always small for in one case (Fig. 9) it attained a diameter of 1 centimeter.

It should be mentioned here that aside from the deep anastomoses mentioned there exists a series of superficial venous circles connecting the femoral with other veins. Reference is made to the upper end of the saphenous and its tributaries which, when dilated furnish large anastomoses from the femoral to the veins of the trunk and axilla.

SUMMARY AND CLINICAL CONCLUSIONS

The femoral vein may vary in its relation to the femoral artery occasionally lying anterior or lateral to that vessel. Rarely it may course for a variable distance in the posterior thigh. Collaterals of the vein are extremely frequent in its lower course and occasionally a collateral may be large enough to constitute a doubled femoral vein.

The deep veins of the thigh join the femoral as several trunks rather than as a single one. The deep femoral vein is formed by a fusion of the venae comitantes of the perforating arteries and only seldom receives the lateral or medial femoral circumflex veins which enter the femoral vein separately. Each of the circumflex veins may exist as two or three vessels. The deep external pudendal vein may join the medial femoral circumflex, or the femoral vein directly.

In identifying the tributaries of the femoral vein the level of termination of each vessel is of some value. The deep femoral vein enters the femoral vein at an average of 8 centimeters or four finger breadths below the inguinal ligament. The lateral femoral circumflex vein enters the femoral above this point, and the medial femoral circumflex at a still higher level—approximately that of the saphenous termination. The inguinal ligament used as a point of reference here is not usually identified during life and the crease of the groin may be deceptive, since it descends with an increase of bodily fat. The pubic tubercle is a better landmark. It lies about 2 centimeters below the part of the ligament referred to in this study.

The lower deep femoral vein was found to have a gross communication with the femoral in 10 per cent of our limbs. There is thus great danger of extension of a thrombus along the deep vessel when the popliteal or lower fem-

Fig. 8. Varieties of valve arrangement in the gross anastomotic channels from femoral to iliac veins. Exceptional arrangement allowing uninterrupted centripetal flow is present in the medial femoral circumflex veins in a and in d, and in the lateral femoral iliac circle in b, in c, and in d.

oral vein is thrombotic. This fact suggests that the femoral should always be interrupted *above* the termination of the deep vein. The other veins entering the femoral have fewer possible connections with a process at the popliteal or lower femoral level. It is only when thrombosis exists in the upper part of the femoral vein that interruption need be done above the ending of the femoral circumflex veins.

Two other factors may influence the choice of the level for interruption of the femoral vein. They are the amount of the blood mass impeded and the anastomotic channels available at various levels.

Three levels at which it is practicable to divide the femoral may be considered in this connection.

1. *Below the termination of the deep femoral vein.* This ordinarily gives rise to little or no

Fig. 9. Gross anatomy of the femoral vein and its arrangement in the main anastomotic channels from femoral to iliac veins. The left femoral enters the pelvis normally but terminates in the hypogastric vein. A small external iliac vein is present. An unusually large lateral femorotibial circle is present in the right thigh. On both sides this structure is valved centripetally (unusual). The circles formed by the medial femoral circumflex and obturator and gluteal veins are valved toward each parent trunk.

venous obstruction. Comparatively little blood mass is impeded and the deep femoral vein constitutes a good anastomotic channel. Collateral femoral veins when present are likewise good anastomotic pathways because they too are valved for centripetal flow. They suffer from their usual failure to reach upward high enough to cross this point of vein division. Interruption at this level will fail to close off pathways for embolism in 10 per cent of individuals.

2. *Above the deep femoral but below all or the major number of lateral and medial femoral circumflex channels.* This interruption has the merit of not trapping the large amount of blood carried by the circumflex or the saphenous veins. Moreover the saphenous is sub-

jected to minimal dilatation. Interference with blood flow nevertheless may be considerable because of the usual paucity of gross anastomoses across this level. The largest path available is formed by the chain of veins in the posterior thigh contributed to by the deep femoral vessels and ending in both femoral circumflex vessels, and the inferior gluteal above. The valves in these veins are oriented toward each parent trunk, rather than in an uninterrupted upward direction, and the lower parts would require a period of venous dilatation before their valve resistance would be obviated.

3. *Above the level of the saphenous and both femoral circumflex veins.* This is an alternative position for interruption above the deep fem-

oral termination. In comparison with the previous level mentioned a larger mass of blood is trapped below the ligature, and there is the added disadvantage in the inability of the saphenous to empty itself through its communications except after dilatation overcomes its valve resistance. Theoretically this should lead to the highest incidence of varicose widening of the saphenous.

The advantage of using this level lies in the availability of gross anastomotic routes leading upward to by pass the interruption. The largest of these is a 'venous circle' comprised by the medial femoral circumflex vein anastomosing with the obturator and inferior gluteal veins. Accessory channels medial to the femoral vein consist of the deep external pudendal vessel communicating with the dorsal vein of the penis and the internal pudendal and thus with the pelvic veins. Laterally there is often present a 'lateral femoriliac circle' connecting the femoral to the deep circumflex iliac veins.

The routes mentioned as well as the superficial anastomoses leading from the saphenous to the veins of the trunk and axilla, are most often valved as venous circles, that is, toward each parent trunk, rather than from the femoral upward. This renders the anastomoses unusable as collateral channels until they have undergone dilatation with resulting valvular incompetence.

Femoral division at this level, often produces much more cyanosis and edema than division at either of the two other levels mentioned. Nevertheless in the few cases in which one of us (E. A. E.) has divided the femoral vein at this level the symptoms have subsided in a few hours or days presumably when dilatation of the anastomotic channels has become adequate.

It would be well for surgeons to record carefully the exact level used in operations on the femoral vein based upon a more exact localization than heretofore used. In this way optimal levels of interruption may ultimately be learned.

LYMPH FROM LIVER AND THORACIC DUCT

An Experimental Study

JAMES C CAIN M.D. JOHN H. GRINDLAY M.D. JESSE L. BOLLMAN M.D.
EUNICE V. FLOCK, Ph.D. and FRANK C. MANN M.D. Rochester Minnesota

SINCE 1894, when Starling showed that ligation of the inferior vena cava above the openings of the hepatic veins caused marked increase in the flow of lymph in the thoracic duct, it has been presumed that the liver is the site of origin of a major portion of the lymph present in the thoracic duct. Markowitz and Mann however in 1930 noted that the flow of lymph in the thoracic duct after hepatectomy was diminished only slightly if at all. Their dogs, after hepatectomy made the usual response to administration of lymphagogues, with great increase in the flow of lymph in the thoracic duct.

Few attempts have been made to study uncontaminated lymph from the liver. Most investigators have cannulated the thoracic duct in the neck and indirectly have estimated the flow of hepatic lymph. The purpose of this investigation was to compare in trained dogs the rate of flow and the composition of hepatic lymph obtained directly from a cannula in the lymph vessels of the liver with similar values for lymph obtained from the thoracic duct.

MATERIALS AND METHODS

Dogs weighing 12 to 26 kilograms were used in this investigation. Except in the case of a few studies made with the animals under anesthesia, the dogs were trained to stand while the lymph was collected. The best preparations were in the young dogs. Approximately a third of the operations resulted in satisfactory preparations as evidenced by a free and uniform flow of lymph. In this paper the

term fistula will be used to describe the condition after this operation. The lymph was collected continuously for as long as 50 hours from the liver and 8 days from the thoracic duct.

The cannula used consisted of capillary sized plastic tubing that extended several inches beyond its exit through a tiny stab wound in the body wall. In these investigations polyvinyl resin tubing (transflex¹ size 24) was used. The tubing was flexible, quite elastic, transparent and smooth walled. It could be cut with a knife or scissors as easily as rubber. It did not crack or tear and it could be sterilized by boiling. Small sized tubing was practically inert biologically although it was found that enough plasticizer is present in larger masses of polyvinyl resin substances to cause slight irritation. Probably the most valuable characteristics of this tubing were its flexibility and its tendency to cause only slow clotting of lymph within it.

The end of the tubing which was placed in the lymphatic was cut on a bevel of approximately 45 degrees. The exposed surface of the lymphatic to be cannulated was stripped clean and a tiny hole was made in the presenting surface. While tension was placed on the lymphatic and the hole was held open with a fine seeker of blue glass, the beveled tip of the transflex tube was inserted into the lymphatic. Frequently the first valve of the lymphatic was ruptured or evaded by the glass seeker in which case it was possible to insert a longer length of tubing in the lymphatic. After the tube was in place and the glass seeker with drawn a previously placed ligature was tied about the lymphatic and tubing.

In the dog the lymphatics emerge from the hilum of the liver and, anastomosing freely

TABLE I.—RATE OF FLOW OF LYMPH IN DOGS,
CUBIC CENTIMETERS PER 10 MINUTES

Description of dogs	Determined alternately				Determined separately			
	Liver		Thoracic duct		Liver		Thoracic duct	
	Range	Mean	Range	Mean	Range	Mean	Range	Mean
Anesthetized	1-8	4.5	0-17	7	1-8	4.5	1-11	5.5
Trained, not anesthetized	1-3	2.5	0-8	7.7	1-8	7.7	0-8	5.5
All dogs		4.5		4.5		5		7.5

over the surface of the gastrohepatic ligament run caudally to the hepatic lymph node adjacent to the portal vein (Fig 1). These vessels and the lymph within them are transparent and almost colorless. The lymphatics are thread-sized, have extremely thin and delicate walls and possess valves at frequent intervals. Emerging from the hepatic lymph node and passing dorsally toward the vena cava are a few efferent lymphatic trunks, one of which is usually larger than the others. This largest efferent lymphatic was the one that was cannulated. Occasionally we have seen 2 or even 3 hepatic lymph nodes with variations in the number and anastomotic arrangement of the efferent trunks.

As previously indicated in order to obtain virtually all the hepatic lymph a mass ligature was placed around the entire efferent lymphatic region after the largest vessel had been cannulated. In order to block the few small lymphatics which enter the hepatic node from the duodenum and pancreas, one or more mass ligatures were placed about the afferent lymphatics at the caudal end of the hepatic lymph node.

In a few early studies the thoracic duct was cannulated at the usual site, where it joins the left subclavian vein. When the duct was cannulated near its origin a greater flow of lymph for a longer time was obtained. Recently we have cannulated the duct above the diaphragm where usually it is a single vessel lying behind the descending thoracic aorta. Smaller lymphatic vessels of the retro-aortic areolar tissue were occluded by a mass ligature of this region. Since there are no valves in the thoracic duct, the plastic tubing could usually be

threaded down the duct until its tip was in the cisterna chyli.

RESULTS

The normal rate of flow of lymph in the thoracic duct has been variously estimated as from 1-24 to 270 cubic centimeters, with an average of 4.0 cubic centimeters, per 10 minutes. Estimation, by direct measurement, of the total quantity of lymph produced by the liver has not been made previously. The normal rate of flow of lymph in both the thoracic duct and the liver as determined under various experimental conditions by use of the technique described in preceding paragraphs, is shown in Table I. There is great variation in range of normal rate of flow of lymph both from the liver and the thoracic duct. The rate of flow was increased after anesthesia with ether. Under the conditions of these studies, the liver contributed approximately a fourth to a half of the lymph in the thoracic duct. The rate of flow was apparently greater in large, than in small dogs and in young, than in old dogs. The state of hydration and stage of digestion were also important factors which affected the rate of flow.

The protein content of lymph from different parts of the body varies. Lymph from the leg contains, according to Drinker and Yessley 0.5 to 1.5 grams of protein per 100 cubic centimeters. In the studies reported herein, the value for protein in lymph from the thoracic duct was about half the value for that in blood plasma. The value for protein in hepatic lymph was usually approximately five sixths the value of that in blood plasma. Animals with fistulas either of the lymph vessel of the liver or of the thoracic duct soon gave rather marked evidence of hypoproteinemia. This occurrence is easily understood when it is remembered that, in 24 hours, approximately 280 cubic centimeters of lymph will drain from a hepatic fistula and that approximately 700 cubic centimeters will drain from a fistula of the thoracic duct. There is some evidence that most of the protein in hepatic lymph is newly formed. Loss of weight is conspicuous in dogs with either type of fistula.

That glucose, when injected intravenously acts as a lymphagogue, as indicated by an in-

of these lesions were treated by local surgical eradication, and in some, secondary and even tertiary operative procedures were carried out for the removal of additional polyps. There were no instances in this series in which there was subsequent clinical evidence of malignancy. This would be expected from the arbitrary manner these cases were selected and from the fact that the polyps were excised.

CARCINOIDS

Of the 76 carcinoid tumors found in the gastrointestinal tract 65 were in the appendix, 10 of the remaining 11 took their origin in the rectum and 1 in the stomach. Twelve of the patients were under 21 years old, 44 between 21 and 30, and 9 between 31 and 38. The age distribution in this group is definitely younger than in the carcinoma group. Seven females and 2 negro males were in the series. Detailed information with regard to regional infiltration and extension to neighboring tissues and lymph nodes was available in a few instances, but no attempt was made to evaluate these features statistically because of the sketchy character of the records. There is no instance of fatal outcome nor were any specimens diagnosed as malignant carcinoid. All of these tumors belong histologically to the classical type of carcinoid with the exception of the rectal group, most of which had histologic features similar to those described by Stout under the designation of 'pre-enterochrome argentaffinoma.' There were 10 of these tumors, they were characterized by ribbons of cells arranged in complicated curls and festoons. They were free of lipid substances and attempts to demonstrate silver reducing granules were unsuccessful. Nevertheless, these tumors were classified as carcinoids; they will constitute the subject matter of a separate report. The identification of these lesions evidently proved difficult, for a number of them were regarded as adenocarcinomas at the time of the first examination. None of these lesions was treated by radical measures and so far as is known no case has been complicated by local invasion or metastasis after removal of the carcinoid.

Benign lymphoid polyp. There were 53 cases with the diagnosis of benign lymphoid polyp of the rectum. The lesions conformed clin-

ically and anatomically to those described by Dukes and by Hayes, Burr and Pruitt. The age distribution was 3 under 21 years of age, 16 between 21 and 30, 11 between 31 and 38 years, and 23 unspecified. Three of the patients were female, 2 were negro male. The disease was cured by local removal; there was no record of recurrence or of fatal outcome.

LEIOMYOMAS

There were 17 tumors of smooth muscle origin in the series. Fourteen of these were benign leiomyomas while the remaining 3 were recorded as leiomyosarcomas. The 14 benign tumors occurred in the esophagus (3), stomach (10), and small intestine (1). All 14 were found in males, 4 of them negroes. In most instances these tumors were incidental findings at autopsy; however, several of them produced symptoms which necessitated surgery and death occurred from postoperative complications in 2.

Of 3 leiomyosarcomas in the series, 2 arose in the stomach and 1 in the small intestine. One of the gastric tumors occurred in a 24 year old female; the lesions were multiple and varied from 2 to 4 centimeters in diameter. The other occurred in a 27 year old white male; the tumor was 6 centimeters in diameter. The specimen from the small intestine, 5.5 centimeters in diameter, was obtained from a 22 year old colored male.

LYMPHOMAS

A detailed consideration of the instances of involvement of the gastrointestinal tract by tumors of the hematopoietic system will be incorporated in the general survey on lymphoid tumors. For the purposes of this study it suffices to note that 22 tumors belonging to this group were coded. Five tumors of the group were seen in persons under 21 years of age, 14 in those between 21 and 30, and 3 between 31 and 38 years of age. Sixteen of the lymphomas were classified as lymphosarcoma, 4 as reticulum cell sarcoma, and 1 each as leucemia and Hodgkin's disease. They were distributed anatomically as follows: lymphosarcoma and reticulum cell sarcoma—4 in the stomach, 6 in the small intestine, 1 in the appendix, and 4 in the large intestine. There

crease in the rate of flow of lymph in the thoracic duct has been known for many years. It had been assumed under these circumstances, that most of the increase in quantity of lymph originated in the liver. In the studies reported herein determinations were made of the effect of intravenous injection of 20 per cent solution of glucose at a rate of 0.5 gram of glucose per kilogram of body weight, into 12 dogs with a lymphatic fistula of the liver and into 8 dogs with a fistula of the thoracic duct. In every instance an increase in the rate of flow of lymph from the liver and thoracic duct occurred. In both groups the rate of flow began to increase during the first 10 minutes after administration of glucose and reached a peak within 30 minutes. On the average the increase from the hepatic fistula was 68 per cent and that from the fistula of the thoracic duct was 75 per cent. The difference between these two percentages is probably not significant. In one dog with a fistula of the thoracic duct injection of 50 per cent solution of glucose at a rate of 1.5 grams of glucose per kilogram of body weight was followed by an increase of 350 per cent in the rate of flow of lymph.

Studies were made to determine the relative changes in the sugar content of blood plasma and of lymph of fasting dogs after intravenous injections of glucose (Fig. 2). In fasting dogs before injection of glucose the sugar content of lymph from the liver and thoracic duct was, on the average about 10 to 20 milligrams per 100 cubic centimeters greater than that of blood plasma. Five minutes after intravenous injection of 20 per cent solution of glucose at a rate of 0.5 gram of glucose per kilogram of body weight the sugar content of lymph from the liver was approximately 50 milligrams per 100 cubic centimeters higher than that of lymph from the thoracic duct. When the rate of flow of lymph from the two sources is considered this finding would appear to indicate that glucose was more diffusible through the capillary bed of the liver than through that of the remaining part of the body drained by the thoracic duct.

Study of the effect of feeding was made on 5 dogs with a lymphatic fistula of the liver and on 18 with a fistula of the thoracic duct. The rate of flow of lymph which was increased in

Fig. 2. Effect of intravenous injection of 0.5 gram of glucose per kilogram of body weight on the sugar content of hepatic lymph, of lymph from the thoracic duct and of blood plasma.

all instances after feeding reached a peak during the second hour and remained greater than the rate before feeding for at least 5 hours. The type of meal fed was not important. The rate of flow of lymph from the liver was increased approximately 108 per cent and that from the thoracic duct approximately 79 per cent over normal. The difference between these two percentages is probably not of great significance.

The effect of brief exercise on flow of lymph was studied. The dogs were allowed to walk on the level at a rate of 40 yards per minute and the rate of flow of lymph was noted at intervals of 5 and 10 minutes. These studies were made on 5 dogs with a lymphatic fistula of the liver and on 8 dogs with a fistula of the thoracic duct. The increase in the rate of flow of lymph from the liver was approximately 83 per cent and that from the thoracic duct was approximately 270 per cent over normal. This result would be expected because of the effects of muscular movement and of massage in the region of the large lymphatic bed drained by the thoracic duct.

The chloride content of hepatic lymph and that of lymph from the thoracic duct were essentially the same and were consistently 10 to 40 milligrams per 100 cubic centimeters greater than that of blood plasma.

The values for inorganic phosphate in the lymph from the liver and thoracic duct and in blood plasma were approximately the same but the value for alkaline phosphatase in the lymph from both the liver and the thoracic duct was consistently 30 to 50 per cent less than the value for that in blood plasma.

Studies were made to determine the effect of acute and chronic poisoning with carbon tetrachloride on the flow of lymph. Two dogs were permitted to breathe for 1 hour a mixture of carbon tetrachloride and air the mixture which consisted of 1 cubic centimeter of carbon tetrachloride per 10 liters of air was circulated at a rate of 10 liters per minute. There was slight if any increase in the rate of flow of lymph from either the thoracic duct or the lymphatic vessel of the liver after this exposure. The lymph from the liver in all instances was distinctly bloody.

The lymphatic vessel of the liver was cannulated in 2 dogs with cirrhosis that had been produced with treatments of carbon tetrachloride 3 times a week for 5 months. The lymphatic vessels of the liver were dilated to an extreme degree, and the rate of flow was increased approximately 10 to 20 times normal. A fistula of the thoracic duct was made in 1 dog in which cirrhosis of 9 months duration had been produced by administration of carbon tetrachloride. In this dog the rate of flow of lymph was only 2 to 3 times normal. In all dogs with chronic carbon tetrachloride poisoning definite evidence of jaundice, ascites, and cirrhosis appeared. The content of bilirubin in lymph was approximately the same as that in blood plasma.

Ligation of the common bile duct resulted in an immediate rise in the content of bilirubin in hepatic lymph. In 2 dogs with fistulas of both the thoracic duct and the lymphatic vessel of the liver the occurrence of an immediate rise in the content of bilirubin in hepatic lymph, with no rise of that in lymph from the thoracic duct, was additional evidence that all the hepatic lymph was being collected.

SUMMARY

The average rate of flow of hepatic lymph was 2.26 cubic centimeters per 10 minutes as compared with 4.6 cubic centimeters per 10 minutes for that of lymph in the thoracic duct. Probably hepatic lymph contributed a fourth to a half the total volume of lymph in the thoracic duct.

Intravenous administration of 20 per cent solution of glucose as a lymphagogue was followed by an increase of approximately 70 per cent in the rate of flow of lymph from both the liver and the thoracic duct.

Ingestion of food and brief periods of exercise were followed in each instance, by an increase in the rate of flow of lymph from the thoracic duct and the liver. Ingestion of food increased the rate of flow of lymph from the thoracic ducts by approximately 80 per cent and that of hepatic lymph by approximately 105 per cent. Exercise increased the rate of flow in the thoracic duct much more precipitously than that from the hepatic fistula, probably because of the massaging effect of exercise on the large lymphatic beds.

Acute poisoning with carbon tetrachloride caused no gross change in the flow of lymph, but hepatic lymph became bloody. In the presence of cirrhosis caused by exposure to carbon tetrachloride the rate of flow of hepatic lymph was greatly increased but that of lymph from the thoracic duct was only moderately increased.

The protein content of hepatic lymph was approximately five-sixths that of blood plasma and that of lymph from the thoracic duct was approximately half that of blood plasma. Lymph from both the liver and thoracic duct contained sugar and chloride slightly in excess of that found in blood plasma. The content of inorganic phosphate was the same in all 3 and the value for alkaline phosphatase was 30 to 50 per cent lower in lymph from each source than in blood plasma.

GELATIN NEPHROSIS

Renal Tissue Changes in Man Resulting from the Intravenous Administration of Gelatin

OLAF A. SKINSNES M.D., Ph.D., New York, New York

THE currently increased interest in and greater use of gelatin as a blood substitute in the treatment of peripheral vascular collapse and as a means of parenteral nutrition demands a careful evaluation of any pathological changes for which this substance may be responsible. Three years ago the appearance of striking tubular hydropic degeneration similar to that seen in sucrose nephrosis (1, 2, 14) but now occurring in the kidneys of patients who had not been subject to sucrose therapy directed our attention to the possible etiologic rôle of gelatin in the production of these lesions. Recently Popper and associates published a report on the use of gelatin in the treatment of shock and noting similar renal tubular swelling in some of their necropsy cases also suggested that these lesions might be attributable to intravenous gelatin therapy. Continued association with a surgical service on which extensive studies of the use of gelatin intravenously have been carried out (4-7) and on which major surgical procedures are a common occurrence has presented an unusual opportunity for the further study of this lesion. The present study was accordingly undertaken in order to evaluate the rôle of gelatin in the pathogenesis of the lesion, to study the morphological nature of the changes which were produced and to appraise their functional significance.

MATERIALS AND METHODS

The study is based on the postmortem examinations of 23 patients who received gelatin intravenously in quantities ranging from 100 to 17,600 cubic centimeters with widely varying intervals between the final injection and the death of the patient. The gelatin derived from pig skin was given in an 8 per cent

From the Department of Pathology, The University of Chicago.

solution in physiological saline usually in doses of 800 cubic centimeters (4).

All the patients save 2 had neoplastic growths primary in the tissues of the abdominal cavity. Of the exceptions one suffered with a squamous cell carcinoma of the lower lip and the other from a chronic bleeding gastric ulcer. All but 3 died of their primary disease and its complications or from complications resulting from the surgical procedures most of which involved extensive regional resections. In most instances the gelatin therapy was given in association with the surgical procedures and either instituted as part of the preoperative preparation or more commonly begun at and continued for varying intervals following the operation.

The postmortem examinations were all performed within 17½ hours of death in the majority of instances the postmortem interval was 2 to 10 hours. Blocks of renal tissue were fixed in Zenker's solution at the time of necropsy, embedded in celloidin and sectioned at 8 microns. The tissues were stained with Heidenhain's iron hematoxylin, Heidenhain's modification of Mallory's phosphotungstic acid hematoxylin and Delafield's hematoxylin-eosin stain. In 1 case No. 6507, alcohol fixed tissues were stained with Best's carmalum for glycogen.

PATHOLOGICAL RENAL CHANGES

Grossly kidneys with well developed gelatin nephrosis are swollen and the cut surfaces tend to bulge. The average weight of 17 otherwise relatively normal kidneys from 10 patients (excluding the kidneys of these patients which showed any neoplastic infiltration) in this series who demonstrated well developed microscopic lesions was 210 grams.

Microscopically the lesions are similar to those described for sucrose nephrosis (Fig. 1)

Fig. Case 6558. The general pattern of the renal lesion in sucrose nephrosis. The patient received 80 cubic centimeters of 50 per cent sucrose solution intravenously 20 hours before death. There is marked acclimation of the convoluted renal tubules. Compare with Figure 3 Hedenbuhl's modification of Mallory's connective tissue stain X 60.

(1-2-14) Variations in the extent and the degree of change can be roughly correlated with the time elapsing between the injection of the gelatin solution and the examination of the kidney and with the amount of gelatin given (Table I). The epithelial cells of the proximal convoluted tubules present a granular finely vacuolated swelling often so severe that the tubular lumens are evident only as slits (Fig. 2). Occasionally the affected cells are necrotic but this change is minimal and the cells are, on the whole, well preserved. In fresh well fixed tissues the brush border remains distinct and is not sloughed. These changes are largely confined to the proximal convoluted tubules and the portions of these tubules which lie in the medullary rays and extend into the renal medulla show the earliest and most pronounced swelling and vacuolization. The distal convoluted tubules may also be affected though to a lesser degree, but the loops of Henle and the collecting tubules remain free from this change even in the severest gelatin nephrosis encountered (Figs. 3 and 4). Best's carmalum stain on the alcohol fixed kidney sections of Case 6507 gave no evidence of glycogen in the hydropic tubular cells.

The lumens of the convoluted tubules and of the glomerular spaces contain much amorphous granular precipitate. This may be indicative of dysfunction, tissue necrosis, or of

the presence of gelatin in the tubular lumens, but its significance is obscured by the fact that such precipitates are routinely encountered in the tubules of otherwise normal kidneys examined at necropsy.

No significant glomerular changes have been noted which are not attributable to other renal changes. Changes such as the leucocyte infiltration and shrinkage of glomerular tufts described by Anderson and Berthia (2) for sucrose nephrosis have not been seen. One case (Case 6412 Fig. 5) having well developed gelatin nephrosis together with a complicating icteric nephrosis, displayed a striking cuboidal epithelial metaplasia of the parietal layer of Bowman's capsule adjacent to the neck of the convoluted tubules. This change is morphologically similar to that which has been described by Anderson and Berthia for sucrose nephrosis and to that which has been described by Bywaters and Dible as occurring in association with the renal lesion of the crush syndrome.

In a number of instances large amounts of gelatin were administered over long periods of time, the greatest amount being 17 600 cubic centimeters administered in 23 doses over a period of 34 days. One case only (Case 6305 Fig. 6) showed moderate focal collobal droplet degeneration of the tubular epithelium. In other instances where varying amounts of gelatin were given but discontinued sufficiently long before death to allow the hydropic swelling to subside (Table I) no changes definitely attributable to the previously existing gelatin nephrosis were demonstrable. The changes seen were such as are routinely encountered in relatively normal kidneys of patients dying with high fever or other generalized disturbances. Only occasional tubules were necrotic displaying pyknotic nuclei and isolated foci of regenerating tubular cells.

FACTORS INFLUENCING THE DEVELOPMENT OF GELATIN NEPHROSIS

Table I summarizes the major findings pertaining to the degree of gelatin nephrosis, the extent of gelatin therapy, other hypertonic intravenous fluids given, and the basic pathological condition of the patient as well as any renal change other than the gelatin nephrosis.

Fig. 2. Case 6206. There is marked hydropic swelling of the illustrated proximal convoluted tubule. The brush border is intact. On the whole the cells are well preserved. Heidenhain's modification of Mallory's connective tissue stain. $\times 655$

Fig. 3. Case 6206. The general pattern of the lesion of gelatin nephrosis in the renal cortex. The proximal convoluted tubules display marked vacuolization; the loops of Henle remain free from such change. Heidenhain's modification of Mallory's connective tissue stain. $\times 160$

It reports all instances of patients receiving gelatin which were encountered in this study.

The most important single factor determining whether or not gelatin nephrosis was present was the time interval between gelatin administration and death. All cases examined within 67 hours of receiving their last gelatin injection showed gelatin nephrosis. No patient expiring more than 120 hours after receiving the last gelatin injection displayed the change. In this connection it is interesting to recall the recent work of Little and Dameron indicating that in dogs given gelatin intravenously only traces of gelatin can be found in the urine after 72 hours. The shortest interval between gelatin administration and death was seen in Case 6317 where the elapsed time was given as 5 minutes in the nursing notes. Though there is basis for questioning the exactness of this figure it is certain that the gelatin was given less than 30 minutes before death. The lesions in this instance were well developed but present only focally in portions of the proximal convoluted tubules lying in the medulla (Fig. 7). The spotty distribution of these lesions is in harmony with recent studies indicating that the individual nephrons each function only part of the time. Their appearance so shortly after the injection of gelatin agrees well with the observation of Little and Dameron that in dogs 50 per cent of the gelatin injected intravenously disappeared from the plasma within 30 minutes.

By the third postinjection hour the proximal convoluted tubules exhibited well developed and widespread lesions. These convoluted tubules then persisted as long as gelatin was administered.

Inspection of Table I reveals that some correlation is possible between the severity of the lesion and the amount of gelatin given in that the severest lesions (4 plus) tend to be present in the instances where the greatest amount of gelatin was given. This correlation is not absolute (see Case 6206) factors of length of postinjection interval and individual variability tending to obscure the picture.

Fig. 4. Case 6206. The general pattern of the lesion in the cortex and medullary rays in gelatin nephrosis. The proximal convoluted tubules show marked vacuolization and many are filled with granular debris. The longitudinal section of a loop of Henle illustrated shows no vacuolization. Heidenhain's modification of Mallory's connective tissue stain. $\times 100$.

Fig. 5. Case 642. Cuboidal metaplasia of the parietal cells of Bowman's capsule. The kidneys showed combined gelatin and ischemic nephrosis. Heidenhain modification of Mallory's connective tissue stain. X200.

Fig. 6. Case 6503. Colloid droplet degeneration of proximal convoluted tubules. 10,650 cubic centimeters gelatin given intravenously in 13 injections in 6 days. Heidenhain modification of Mallory's connective tissue stain. X400.

Rigdon and Cardwell suggested that the state of hydration of the patient is of importance in determining the occurrence of sucrose nephrosis. The material available did not permit an evaluation of this factor in the pathogenesis of gelatin nephrosis. This series is also not sufficiently extensive to permit judgment as to whether or not previous renal disease will enhance the lesion.

EFFECT OF GELATIN NEPHROSIS ON RENAL FUNCTION

No consistent accurate measure of renal function was made on these patients clinically since they did not evince clinical renal dysfunction. The occasional pertinent blood and urine studies recorded gave no substantial evidence of impaired renal function. A careful study of the fluid balance of the patients was made from the clinical records. These studies were frequently complicated by the fact that in most instances the gelatin therapy was begun at the time of operation. Concurrently increased fluid administration and fluid and blood loss through inadequately measured emesis and drainage and from surgical loss of blood often obscured possible changes such as the early diuresis noted by Bridger and associates in dogs receiving intravenous gelatin.

Case 6532 (Fig. 8) demonstrated the most striking change which might possibly be attributed to gelatin therapy. A marked diuresis occurred 12 days after laparotomy on the

third and last day of gelatin administration. This persisted for 6 days and then subsided. The only other intravenous fluid administered during this time was 5 per cent glucose solution and no other medication was given which might be held accountable for the diuresis. Comparable quantities of glucose were given daily from the third postoperative day (14 days before the diuresis developed) through the twenty-second postoperative day (the day the diuresis subsided). A second patient (Case 6542) had a satisfactory urine output of 1000 cubic centimeters on the second postoperative day. On the third day he was given a first injection of 400 cubic centimeters of gelatin solution intravenously. His urine output on this day dropped to 50 cubic centimeters despite a total of 4900 cubic centimeters of intravenous fluid given. On the 2 succeeding days he received a total of 6,650 cubic centimeters of fluid intravenously including 400 cubic centimeters of gelatin but put out only 100 cubic centimeters of urine per day and expired on the sixth postoperative day without having established adequate urine output. The day before his death blood chemistry studies showed serum chloride 108.5 millimoles per liter serum pH 7.32 serum carbon dioxide 18.5 millimoles per liter and blood nonprotein nitrogen of 117.6 milligrams per cent. The only significant lesion in the kidneys at necropsy was gelatin nephrosis. A complicating factor in the interpretation of these findings was the myocardial infarction

TABLE I—SUMMARY OF THE SEVERITY OF GELATIN NEPHROSIS, THE AMOUNT OF GELATIN THERAPY GIVEN OTHER INTRAVENOUS THERAPY EMPLOYED AND THE BASIC PATHOLOGICAL CONDITION OF THE PATIENTS STUDIED

Case No.	Gelatin nephrosis	Interval between last gelatin and death	Total c.c. gelatin given	No. of doses	Total days of gelatin therapy	Other hypertonic fluids	Remarks
Gelatin Given—Gelatin Nephrosis Present

Fig. 7. Case 637. Early focal gelatin nephrosis. There is well developed vacuolization of the convoluted tubules. The patient received 80 cubic centimeters of gelatin intravenously 1/2 hour of his death. Heidenhain modification of Mallory connective tissue stain. $\times 60$.

developing on the third postoperative day. His blood pressure subsequently remained at about 86/60 to 100/80 (preoperative pressure 145/80) till the day of death.

DISCUSSION

Three of the cases presented raise the question of another possible effect of gelatin injection. Case 6306 had suffered from several attacks of indigestion during the past few years. On April 5, 1944 at 2:30 p.m. he was given 800 cubic centimeters of gelatin intravenously. Throughout the following day he had vague abdominal distress and mild substernal pain, felt nauseated and noted excessive sweating. At 2:45 p.m. of this day intravenous injection of 800 cubic centimeters of gelatin solution was begun. After receiving about 200 cubic centimeters he complained of severe substernal pain, became cyanotic and his breathing became shallow. Two hours later he complained of severe epigastric pain boring to the back, his blood pressure was unobtainable and at 10:35 p.m. he expired with extensive myocardial infarction demonstrated at necropsy. Another patient (Case 6542) was found cold and sweating on the morning of his third postoperative day. His blood pressure was 70/60. Saline, blood antigen and 400 cubic centimeters of gelatin solution were given intravenously. Seventeen and a half hours later he was given an additional 400 cubic centimeters of gelatin and 1000 cubic

centimeters of antigen. 67 hours later he expired with extensive myocardial infarction. Both patients had severe coronary arteriosclerosis. The third (Case 6485) developed thrombosis of left iliac vein and artery postoperatively while receiving gelatin and other fluids intravenously and died of pulmonary embolism 24 hours after the last gelatin injection.

Intravenous injection of gelatin is known to produce circulatory changes. Fletcher and associates as well as Holt and Knoefel demonstrated an increase in blood volume greater than the volume of gelatin injected, this apparently being due to the effect of gelatin in drawing additional fluid into the circulation. The former investigators did not note any excessive strain on the cardiovascular systems of their patients or volunteer subjects though they did note a marked increase in cardiac output and a sustained hemodilution. They urged caution in the use of gelatin and other macromolecular substances in chronically ill patients. Handik and Karsner demonstrated pseudoagglutination of erythrocytes in the form of conglutinated thrombi in postmortem sections of a guinea pig receiving 0.5 per cent gelatin intravenously. Ivy and associates noted similar marked pseudoagglutination and an increase in the sedimentation rate in dogs given 5 per cent gelatin solution intravenously. Similar observations on patients have been reported by Kozoll and associates (19, 25). Earlier reports (24) indicated that gelatin given intravenously increases the viscosity and coagulability of the blood. Subcutaneous injections of gelatin have been used in the past to increase the coagulability of the blood in the treatment of aneurysms. Recently Koop and associates following an extensive investigation reported that the clotting time after gelatin infusion is uniformly prolonged in dogs but was unaffected in 6 of 7 patients studied. The seventh patient demonstrated an appreciably prolonged clotting time. Stugmann and associates found no pathological changes in bleeding time, clotting time, or platelet counts of patients given gelatin infusion and Gordon and associates found no postmortem evidence of thrombosis, hemolysis, embolism or capillary damage in dogs given 8 to 10 per cent solutions of gelatin intravenously.

Fig 8. Case 6532 L.B. Fluid balance record. Total Intake \circ — \circ total output, \circ +--+ \circ urine output, \circ --- \circ gelatin given ———

In the light of these reports conflicting though the conclusions sometimes are the 3 cases reported above though not conclusively implicating gelatin suggest the need for caution against the indiscriminate use of gelatin intravenously administered to patients with circulatory disturbances and vascular disease. It may be that some of the conflicting reports may be due to the variability of gelatin preparations. A report by the National Research Council indicates that at least some of the local thrombotic effects reported may be due to added preservatives.

This series of necropsy studies would seem clearly to establish the etiological rôle of gelatin in the production of hydropic swelling of renal tubules. Well developed lesions were found in all postmortem examinations of kidneys of patients receiving gelatin intravenously within 67 hours of the time of death. Hepper found similar lesions in dogs given gelatin solution intravenously. Similar well developed lesions were not found in over 400 consecutive cases studied except in those in

stances in which sucrose therapy had been employed. Minimal lesions were occasionally encountered which corresponded to the minimal lesions seen in some of the patients who had received gelatin so long before death that the residual changes could only be attributed to gelatin by inference. The etiology of these changes was not clearly demonstrated but the changes were such as might be attributed to other intravenous fluids.

The effect of other intravenous fluids was evaluated. Cutler reported finding hydropic changes in the kidneys of patients receiving hypertonic solutions of dextrose (10-15 per cent solutions). Nearly all the patients in our series received dextrose intravenously, some receiving relatively large amounts of 10 per cent solution over long periods. This may in some instances have enhanced the effect of the gelatin but other patients receiving similar amounts of dextrose without concomitant gelatin showed only minimal or equivocal tubular vacuolization. Five of these patients received 50 per cent dextrose intravenously

usually in 1 or 2 doses of 50 cubic centimeters each during the week preceding their demise. No tubular lesions were found. One patient (Case 6233) received 250 cubic centimeters of 50 per cent dextrose during the 48 hours before death but displayed no renal lesion at necropsy. Amigen was frequently administered together with gelatin. A number of control cases receiving amigen without concomitant gelatin failed to demonstrate nephrotic renal changes.

The pathogenesis of gelatin nephrosis is not demonstrated by this study. Wilmer in discussing the mechanism of sucrose damage to the kidneys concluded that this effect was osmotic, the sucrose diffusing into the renal tubular cells and drawing in water. He noted that rats and rabbits phloridzinized to prevent sucrose reabsorption still developed hydropic changes of the renal tubules. It is probable as also suggested by Popper and associates that gelatin nephrosis develops in much the same manner the gelatin arriving in the tubular cells by diffusion or active absorption or both and causing in turn the taking up of water by increased osmotic pressure exerted by the gelatin. The ready reversibility of the change in both cases speaks in favor of this concept.

Though no uniform, clearly demonstrable harmful effects have as yet been attributed to gelatin nephrosis, it is well to bear in mind the growing feeling that the morphologically similar sucrose lesion is not innocuous. Feher and associates reported that in dogs having an initial large renal reserve, no demonstrable effect on the blood nonprotein nitrogen was found when sucrose was injected though the ability of the kidneys to concentrate urine was reduced. In dogs with relative renal excretory insufficiency produced by Goldblatt's method of producing hypertension or by temporarily occluding the renal arteries for 1 hour marked reduction in the ability to concentrate urine and a transient rise in blood nonprotein nitrogen occurred when sucrose was injected intravenously. A report by the National Research Council points out that it is not known whether the use of gelatin will impair functional return to normal in kidneys in sustained ischemia or severe burns or in the crush syndrome. Anderson and Bertha (2) recommend

that sucrose be withheld from patients with renal lesions and state that it should in no instance be given in large or repeated doses. The 2 cases reported as showing diuresis and oliguria in the presence of gelatin injection, warrant a similar caution in the use of gelatin.

SUMMARY

1 The postmortem findings of 23 patients receiving intravenous gelatin therapy who expired as a result of medical and neoplastic disease or from complications of therapeutic surgical measures, are reported as demonstrating the etiologic rôle of gelatin in the pathogenesis of renal hydropic changes morphologically similar to those produced by the intravenous injection of sucrose.

2 The morphology of the renal lesion produced by gelatin is described and compared with that of sucrose nephrosis.

3 Gelatin nephrosis is shown to be a reversible change occurring within half an hour after the intravenous injection of gelatin and disappearing within 120 hours following the last injection.

4 Studies of the effect of the renal lesion on renal function are reported as inconclusive but 2 suggestive cases are discussed one showing diuresis and the other oliguria following the intravenous administration of gelatin. Caution is suggested in the use of this substance in patients exhibiting previous renal impairment.

5 Attention is directed to the possible rôle of gelatin in promoting circulatory disturbances and 3 cases are reported as suggesting gelatin as a potential precipitating factor in coronary occlusion and vascular thrombosis in the presence of circulatory disturbances and vascular disease.

found to have a duodenal ulcer from which gas escaped into the tissues. Three cases of endometrios were reviewed 2 of the lesions were in the appendix and the other in the ileum.

SUMMARY AND CONCLUSIONS

A general survey of the tumors arising in the gastrointestinal tracts of members of the armed forces between 18 and 38 years of age has been made. The results of this survey as to relative frequency and anatomic distribution is largely summarized in the accompanying tables and charts. These overall figures follow those of previous reports. The most salient features brought out are these:

1. Carcinomas of the large intestine and rectum constituted over three-fourths of all of the carcinomas of the gastrointestinal tract.

2. Carcinomas were most frequent in the older age group but mortality was relatively higher in the younger age group.

3. Polypoid lesions of the intestinal tract were observed most commonly in the rectum.

No recurrences resulted after local excision.

4. Carcinoids occurred most frequently in the appendix, but those in the rectum were commonly confused with carcinomas.

5. The most frequent tumor of the lymphoma group was the benign lymphoid polyp.

These tumors were commonly found in the rectum and local excision was followed by no subsequent evidences of recurrence or transformation into the malignant type.

were 5 instances of multiple tumors. The granuloma of Hodgkin's disease was in the small intestine and the ileocecal lesion was among the 20 cases of reticulum cell sarcoma and lymphosarcoma, and another in the case of leucemia. Follow up records in the case of Hodgkin's disease were incomplete. Five of the lymphoid tumors were seen in individuals under 21 years of age, 14 in those between 21 and 30 and 3 in those between 31 and 38.

MISCELLANEOUS

Among the less common tumors in this survey there were 7 malignant melanomas, 6 of them metastatic in origin only 1 was believed to have arisen in the ileum. Four neurofibromas were located in the appendix and were discovered at operation for what appeared clinically to be acute appendicitis. One gallbladder carcinoma of the cocoon occurred in a 6 centimeter in diameter. In the instance of benign tumors recorded the lesions were multiple and were located in the ileum. One unusual gastric tumor was a hemangio-pericytoma and undifferentiated sarcoma of the stomach and undifferentiated sarcoma of the jejunum. Lipoma, myxoma, lymphangioma, teratoid and other tumors, sometimes reported to occur in the gastrointestinal tract, were not observed in this series. The reason for this probably lies in the screening system previously described.

There were 8 cysts of the gastrointestinal tract, 4 related to the esophagus and 4 to the small intestine. Three of those in the esophagus were lined by respiratory epithelium and 1 was a parasitic cyst due to ankylostomiasis. Of the 4 in the small intestine the other 3 were enteric cysts lined by columnar epithelium. One mucocle was seen in the rectum it was associated with a polyp. Of interest, too was a case of pneumatoxis cystoides intestinalis for which a segment of ileum was resected. The patient was subsequently

SODIUM PENTOTHAL ANESTHESIA FOR SELECTED VAGINAL OBSTETRICS

A. LOUIS DIPPEL, M.D. R. J. HELLMAN M.D. C. E. WOLTERS, M.D.
H. A. WALL, Jr. M.D. and F. H. HAIRSTON M.D. HOUSTON TEXAS

In order to complement local anesthetics, we scanned the field for an anesthetic agent with reasonable safety whose technique of administration could be mastered with little extra instruction whose contraindications were few and which might be administered to private patients in view of the fact that relatively very few of our private physicians ever used local anesthetics even though adequate equipment for its use was immediately available. One of us (A. L. D.) had employed intravenous sodium pentothal anesthesia routinely for minor and for selected major gynecological operations for a number of years and had observed its routine use for vaginal obstetrical deliveries. The choice of this drug as an anesthetic agent for selected vaginal obstetrical deliveries has proved most gratifying to both house staff and private physicians although none of the latter early employed it with milking.

Sodium pentothal is a barbiturate which differs little in chemical structure from pentobarbital sodium (nembutal) sodium amytal and crystal soluble being most like nembutal. Induction of anesthesia is incredibly short and quick, the patient generally being unconscious within 20 to 30 seconds and ready for surgery within a minute after the first few cubic centimeters of solution have been administered into the vein. Vomiting during or after its administration is rare. Recovery is rapid to 3 hours after anesthesia depending in large measure upon the amount of premedication. There is seldom any hang over reaction. It is rapidly destroyed in the body probably by the liver although Lundy (10) has suspected it in the urine. It does not have any effect upon the blood chemistry except for a practically negligible elevation of blood sugar. The blood picture is unaltered and metabolism unaffected. It produces a moderate respiratory

The use of intravenous sodium pentothal in obstetrics is not new. Several literature during the past 10 years (3, 5, 8, 9, 12, 14) Some have employed it as the sole or major anesthetic agent routinely or almost routinely in obstetrics (3, 8, 12) whereas Labrecque reserved it for use in cases with severe upper respiratory infection bronchitis, asthma, tuberculosis, bronchiectasis, and after ingestion of large meals. Hunt and Lundy employ it in connection with local infiltration for cesarean section withholding the use of pentothal until the abdomen has been entered and the operator is ready to proceed with incision of the uterus and immediate extraction of the fetus. Several (8, 9) contend that it is an unsatisfactory anesthetic agent for podalic version with extraction on the grounds that the relaxation which it produces is inadequate. Hellman (5) and Rucker (11) do not agree with this contention in view of the fact that 1.5 per cent of Hellman's operative deliveries and 7.3 per cent of Rucker's deliveries involving a viable infant were effected by this method.

Our use of intravenous sodium pentothal during World War I because of the shortage of anesthetics available for routine ward deliveries. It had been immediately preceded by essentially routine use of perineal block anesthesia. Originally open drip ether was given by various untrained hospital employees, but this was abandoned after the occurrence of a serious case of vomiting under ether anesthesia followed by aspiration pneumonia which necessitated hospitalization of the patient for almost 3 months. That older members of the staff could not recall other similar tragic or near tragic cases is truly remarkable.

From the Division of Obstetrics, Herman Hospital and the Department of Obstetrics, Baylor University College of Medicine.

depression with anesthetic dosage but this is not alarming. Pentothal will effect an elevation of blood pressure particularly systolic but the elevation is not sustained though the immediate systolic rise may amount to as much as 20 millimeters of mercury (8). It leaves the pulse unaffected or somewhat slower. Other pharmacological characteristics have no clinical bearing. Laryngospasm is frequently mentioned as an effect of intravenous sodium pentothal anesthesia but actually appears to be rather uncommon more particularly when its use is preceded by a hypodermic of atropine or of hyoscine.

Intravenous sodium pentothal rapidly traverses the uteroplacental barrier to depress fetal respiratory movements and to retard the initiation of respirations in the newborn. Hellman, Shettles, and Stran (4) found that within 10 or 12 minutes it reaches equal concentrations in fetal and maternal blood. They found that during the first 5 minutes after beginning the anesthetic, little of the drug reached the fetus. Dresbach and Snyder showed that when the experimental rabbit was given 10 milligrams of pentothal intravenously per kilogram of body weight at term, the fetal respiratory rate was decreased to one-third the initial rate for a period of about 5 minutes, and that after a total dose of 3 to 5½ times the above amount there was relatively little cumulative effect upon the fetus. In this connection it should be pointed out that the above smallest experimental dose is comparable to the average total dose used in our series.

It has been suggested that intravenous sodium pentothal should be avoided as an anesthetic in certain toxemia patients because of the presumed destruction of the drug by the liver and the possibility of added degenerative changes in that organ (11). The frequent moderate elevation in systolic blood pressure might also be used as an argument against its use in connection with the severe hypertensive toxemias of pregnancy. However, Rucker (13) seems not to have considered this maternal complication as a serious contraindication to its use. In general, however, there seem to be few valid contraindications to its use in obstetrics. It is conceded that pentothal with

its respiratory depressant effect is undesirable in heart disease with decompensation with marked anemia, in the face of dyspnea attributable to pathological processes in the thorax or if there is any reason to think that the respiratory passage is, or may become obstructed. It is ideal that the stomach should be empty in order to eliminate vomiting. Also pentothal is known to increase laryngeal reflexes and vomiting would then tend to increase the incidence of laryngospasm. There are individual idiosyncrasies to pentothal but these are surely uncommon. Hunter has reported a case with cutaneous manifestations in the form of erythema multiforme followed by pustule formation and pyrexia when the anesthetic was later repeated. It goes without saying that the solution should be injected intravenously and not into the extravascular tissues nor into the arterial tree. Lundy (10) records several cases of intra arterial injection of sodium pentothal. All of these patients experienced varying amounts of pain in the injected arms. One of these succumbed to an overdose of pentothal. The induction of anesthesia in this case was prolonged with an excessive amount administered. Death followed the delayed entrance of the overdose of the drug into the general vascular system via the arterial as compared with the intravenous route. Lundy advises the use of an intermittent tourniquet to the affected arm and oxygen inhalation whenever a large amount of the drug is administered intra arterially. Dixon and Lundy (10) have indicated that 10 per cent concentrations of sodium pentothal injected into the perivenous or subcutaneous tissues produce pain and irritative manifestations, sometimes even with sloughing of tissue but Jarman claims that 5 per cent solutions are almost innocuous when injected into these tissues and that it is unusual for these patients to complain of even a sore arm. Lundy (10) says that thrombosis was frequent with 10 per cent solutions but that its incidence has been reduced in proportion to the reduction in concentration of the drug.

Between July 24 1945 and October 1 1946 350 patients from both ward and private services of the Hermann Hospital were delivered of viable pregnancies under intravenous so-

TABLE I.—ANALYSIS OF 350 PATIENTS DELIVERED UNDER INTRAVENOUS SODIUM PENTOTHAL ANESTHESIA ACCORDING TO DEPARTMENTAL AFFILIATION AND RANK OF ANESTHETIST

Department	No. patients	Per cent

Professional anesthetist	1	
Totals	350	100.0

Race and economic level, the latter determined from admission status, of each patient in the series will be seen in Table II. The hospital has no accommodations for private colored obstetric patients. The distribution between the races for both ward and private patients is roughly the same as for these services as a whole. Sixteen private physicians delivered patients under intravenous sodium pentothal anesthesia but 9 of these can be considered casually for each accounted for a maximum of only 3 deliveries. This does not mean that the 9 tried and discarded pentothal for short vaginal delivery but that their number of deliveries over the period of time under consideration was correspondingly low. Thirty was the maximum number of deliveries accounted for by any one private physician.

Age of patient is recorded in Table III. Since there was no selection of patients for pentothal anesthesia on the basis of age, the observed age distribution is essentially the same as for the service as a whole. Two patients were less than 15 years old actually each was 14 when delivered.

Mention has already been made of the departmental policy of preferring no analgesia

TABLE II.—RACE AND ECONOMIC LEVEL OF 350 PATIENTS DELIVERED UNDER INTRAVENOUS SODIUM PENTOTHAL ANESTHESIA

and local infiltration anesthesia for the handling of premature labor and delivery. There were however 7 premature births in this series. Two of these involved intrapartum fetal death due to premature separation of the normally implanted placenta, each at 30 weeks gestation. The remaining 5 premature deliveries advanced to 34 weeks (1 case) and 35 weeks (4 cases) gestation were effected with dispatch so that the premature infants with birth weights ranging from 4 pounds 6 ounces to 5 pounds 3½ ounces were born without narcosis, required no resuscitation and were all raised. The remaining 343 (98%) gestations produced near term term, and postmature fetuses, i.e. each newborn was at least technically of term size—weighed at least 2500 grams (5½ pounds).

Table V reveals that there was no selection of patients in regard to previous obstetrical experience. Fifty three per cent were multiparas, only 4 being in the grande multipara range. One of the essential primiparas had had 6 previous abortions, 2 had had 2 each and 14 had each previously aborted once. There were 4 young primiparas, i.e. patients delivering a term or near term pregnancy before the sixteenth birthday anniversary. They

were all ward patients, 1 being a Mexican 15 years old and 3 colored one 15 years, and two 14 years of age. Four patients were true elderly primiparas, i.e. were delivered of the first viable pregnancy after the thirty-fifth birthday anniversary. One of these was a 39 year old private white woman and the others colored patients 36 to 39 years of age. Five were elderly essential primiparas or were delivered of the first term or near term pregnancy after age 35 but in each instance the viable pregnancy had been preceded by 1 or more abortions. Four of these were white private patients each of whom had had 1 previous abortion the oldest was 42 years of age 1 colored elderly essential primipara was 37 years old and had had 2 previous abortions.

The various primary fetal presentations and positions are recorded in Table VI. Manual

TABLE VI.—ANALYSIS OF 350 PATIENTS DELIVERED UNDER INTRAVENOUS SODIUM PENTOTHAL ANESTHESIA ACCORDING TO PRIMARY FETAL PRESENTATION AND POSITION

or forceps rotation from an occiput transverse or posterior to an anterior was employed 35 times.

In Table VII it will be seen that 110 fetuses (31.3%) were delivered spontaneously under intravenous sodium pentothal anesthesia. This figure is almost identical to that reported by Eastman (1) whereas Rucker (13) reports only 8.3 per cent spontaneous deliveries when a viable infant was involved. LaBrecque reports the highest incidence of spontaneous delivery namely 57 of 80 deliveries (71.2%), with the use of either sodium pentothal or evipal soluble. In this connection it must not be forgotten that pentothal will efface bearing down efforts in 60 per cent of the patients anesthetized with it whereas evipal does not unfavorably affect this reflex mechanism (9). The low incidence of podalic version and of midforceps delivery in the current series reflects the conservatism of the service. The version and extraction was performed on the patient with transverse presentation of the fetus and prolapse of the umbilical cord. One midforceps delivery was used for delivery of a second twin while the other 2 midforceps deliveries occurred on the private service. Perineorrhaphy for correction of a previously noted

TABLE VIII.—ANALYSIS OF 350 PATIENT DELIVERIES UNDER SODIUM PENTOTHAL ANESTHESIA ACCORDING TO RANK OF ACCOUCHEUR

Rank of accoucheur	No. patients	Per cent
Rotating Interns	130	37.1
Resident obstetrician	87	24.9
For private physician	1	
With aid of staff physician	2	
Private obstetrician	133	38.0
Private patients	131	
Ward cases	2	
Totals	350	100.0

rectocele was performed in connection with 8 private deliveries. One vaginal and 2 cervical tears were known to have occurred with low forceps delivery and all were repaired under pentothal anesthesia. Forceps to the after coming head were applied in 5 instances. Mauriceau maneuver being employed in the other 6 breech deliveries.

The accoucheur for each delivery is recorded in Table VIII. Only 2 ward deliveries were not actually effected by the house staff—the version with extraction and a difficult low forceps due to an excessive-sized fetus with erythroblastosis associated with a contracted pelvis.

As previously stated, a 2 per cent solution of pentothal was administered intravenously. The amounts of the drug employed are shown in Table IX. Unfortunately the amount used was not recorded in 100 (28.6%) of the cases. Of the remaining 250 in which the exact amount administered is known only 21 (8.4%) received more than 50 cubic centi-

TABLE IX.—ANALYSIS OF 350 DELIVERIES UNDER INTRAVENOUS SODIUM PENTOTHAL ANESTHESIA ACCORDING TO AMOUNT OF DRUG EMPLOYED IN 2 PER CENT SOLUTION

Amount, cubic centimeters	No.	Per cent of total	Per cent of recorded
10 or less	4	1.1	1.6
11 to 30	33	9.4	13.2
31 to 39	56	16.3	14.4
41 to 49	77	22.0	30.8
51 to 59	79	22.6	31.6
61 to 69	5	1.4	2.0
71 to 79	6	1.7	2.4
81 to 89	6	1.7	2.4
91 to 99	1	0.3	0.4
101 to 109	1	0.3	0.4
Above 100	1	0.3	0.4
Not recorded	100	28.6	
Totals	350	100.0	100.0

meters (10 gm.) The largest amount given 135 cubic centimeters (27 gms.) was for the Mexican woman with a contracted pelvis and an excessive-sized erythroblastotic, stillborn (intrapartum death) delivered by prolonged and difficult low forceps extraction. She had received little analgesia. Spontaneous delivery without perineal repair was effected once with only 6 cubic centimeters of solution and a breech extraction of a stillborn premature (intrapartum death) without repair in another instance with 8 cubic centimeters. The average for the series was 39 cubic centimeters (0.78 gm.) In large measure, the amount of anesthesia varied with the amount and recency of administration of analgesia, but such correlations cannot be graphically shown by usual methods. However the various analgesic drugs with time interval between last dosage and moment of birth of the child are recorded in Table X. Of interest are the great variety of drugs and combinations of these used to obtain analgesia. It was rather surprising to discover that 182 patients, 58.7 per cent of those receiving analgesia, received the last dose of the analgesic less than 2 hours before delivery of the infant. Obviously this fact must be remembered when noting the

TABLE X.—ANALYSIS OF 350 DELIVERIES UNDER SODIUM PENTOTHAL ANESTHESIA ACCORDING TO ANALGESIC DRUGS GIVEN AND TIME INTERVAL BETWEEN LAST ANALGESIC DOSE AND BIRTH OF INFANT

Analgesic drugs administered	No. patients	Per cent	Time from last dose to delivery	
			Range, min.	Average, min.
Demerol and hyoscine	5	1.4	10 to 465	80
Demerol alone	80	23.0	10 to 2400	30
Demerol with secobarbital, or luminal	14	4.0	30 to 650	98
Pantopon or dilaudid with secobarbital or luminal	20	5.7	30 to 90	35
Phenobarbital or luminal	6	1.7	80 to 2000	180
Secobarbital or luminal	1	0.3	30 to 465	205
Hyoscine with secobarbital or luminal	1	0.3	30 to 75	33
Codeine or morphine		0.3	140 to 440	240
None	40	11.4		
Totals	350	100		

TABLE XI.—ANALYSIS OF 14 DELIVERIES UNDER INTRAVENOUS SODIUM PENTOTHAL ANESTHESIA ACCORDING TO SUPPLEMENTARY ANESTHESIA EMPLOYED

Perineal block for episiotomy repair	3
Following use of 1 gm. l. pentothal	4
Perineal block	2
Open ether	
Nitrous-oxide	
For partial spontaneous breech delivery	
Perineal block
